ACKNOWLEDGEMENTS

After having my master degree from Tanta University, I got a full funded PhD mission from the Egyptian Ministry of Higher Education in a competitive funding opportunity in 2011. I did not hesitate to contact the soon-to-be my advisor, Dr. Brooks Ellwood, who I worked with in collecting two Paleocene/Eocene boundary sections in Upper Egypt in 2004. I am deeply thankful to him for his continuous support, guidance and advice during the progress of this project. He was extremely helpful from day one when he picked me up from Baton Rouge airport and assisted me settle down, through helping during multiple field trips that were funded from the Robey Clark endowment at Louisiana State University, to reviewing multiple manuscripts.

I would like also to thank Suzanne Ellwood, Eman Eldakkak, Jennifer Kenyon, and Minhee Chou for their kind assistance during the field work and sample collection. I am greatly indebted to Amber Ellwood for her help during samples preparation and measurement for magnetic susceptibility and carbonate contents, and for running selected samples for carbon and oxygen isotopes.

I would like to express my deep gratitude to my committee members, Dr. Samuel Bentley, Dr. Sophie Warny, and Dr. Wei-Hsung Wang for their valuable discussions and suggestions that helped me to expand my expertise over the course of this research.

Finally, this appreciation is extended to my wife, Eman Eldakkak, for her unlimited encouragement and incredible help in so many different ways that can never be repaid.

PREFACE

The goal of this research is to trace and constrain not only the base of the Drumian stage but also the LOOP/FAD of *P. atavus* and the DICE in the HRE. Accounting for lithologic complexity among the three studied sections is a prerequisite for such study. Therefore, this dissertation is divided into three chapters. Each chapter is a stand-alone paper for publication.

Chapter one represents high-resolution lithostratigraphic correlation among the three studied sections based mainly on detailed detrital/carbonate investigations. This paper is the product of research that had four goals. First, to investigate the complex lithological variations and their causes in the HRE among the Drum Mountains GSSP (UT), House Range Marjum Pass (UT), and Snake Range Packrat (NV) sections. Second, to interpret from these data climatic and sea level fluctuations that have caused the lithologic complexities. Third, to determine and refine the depositional setting represented by each section. Fourth, to identify, trace and interpret some of the numerous storm-event layers identified within the HRE.

Chapter two aims to identify lithostratigraphic marker (s) that might be used to trace important surfaces such as the base of the Drumian Stage and the FAD/LOOP of *P. atavus* from the GSSP through the Marjum Pass and into the Packrat section. It also aims to test the synchronicity of *P. atavus* within the HRE, and investigate the reliability of *P. atavus* as biostratigraphic marker for high resolution studies.

Chapter three provides high resolution chemostratigraphic correlation among three slope and basinal sections where hundreds of samples have been analyzed to test DICE synchronicity regionally within the HRE across the base of the Drumian Stage. In addition,

this test is extended to three southern carbonate platform sections (Wah Wah, Panaca Hills and Desert Range). Their published chemostratigraphic data sets (Howley, 2010; Howley and Jiang, 2010) were used.

TABLE OF CONTENTS

ABSTRACT

The Global boundary Stratotype Section and Point (GSSP) of the base of the Cambrian Drumian Stage was defined at 62 m above the base of the Wheeler formation, at the First Appearance Datum (FAD) of *Ptychagnostus atavus* (*P. atavus*), and at 10 meter below the DrumIan Carbon isotope Excursion (DICE) on the Stratotype Ridge in the Drum Mountains western Utah, (Babcock at al., 2004; 2007). Tracing the base of the the Drumian stage to other Middle Cambrian sequences in the House Range Embayment (HRE), a fault-controlled deep-water intrusion into an extensive carbonate platform along the passive margin of western Laurentia, was tentative and uncertain. The complex lithological variations, the absence of lithostratigraphic and other reliable biostratigraphic markers, and the widely-spaced sampling and coarse correlation among HRE sections, have contributed to such uncertainty. This study focuses on regional high-resolution correlation among the Drumian GSSP section, the Marjum Pass section, and the Packrat section. The objective of this research is to account for such complex facies variations, and constrain not only the base of the Drumian Stage but also the Lowest Occurrence Observed Point (LOOP)/FAD of *P. atavus*, and the DICE within the HRE.

The HRE lithological variations follow broad facies patterns. Carbonates dominate at the edges of the HRE and decrease inward, while detrital materials dominate along the HRE trough and decrease outward. Three storm layers helped in tracing important surfaces including the base of the Drumian Stage from one section into the other. Unfortunately, the GSSP was defined based on reworked *P. atavus* specimens at the base of the first storm layer that has an erosional base and is composed of reworked sediments. Therefore, the FAD/LOOP of *P. atavus* is diachronous and its acme is synchronous within the three studied sections. It is

concluded also that the DICE is a chronostratigraphic marker that constrain the base of the Drumian Stage in the embayment and the nearby southern platform sections unless suppressed by the incoming heavy-isotopic platform carbonates. The DICE maximum negative $\delta^{13}C$ excursion is synchronous while the onset and the end of the DICE are diachronous.

CHAPTER I: SEA LEVEL AND CLIMATIC-INDUCED FACIES VARIATIONS IN THE MIDDLE-CAMBRIAN HOUSE RANGE EMBAYMENT, WESTERN LAURENTIA

The Middle-Cambrian House Range Embayment (HRE) represents a deep-water intrusion into an extensive carbonate platform along the passive margin of western Laurentia. The distribution and source of the HRE mixed siliciclastic-carbonate sediments are poorly understood because many key elements have been missed during field observations or coarse correlation. This study accounts for the complex lithological variations in the HRE, and improves our understanding concerning the global climatic and sea level fluctuations that drive these variations. Magnetic susceptibility (χ) and carbonate content ($CaCO_3$%) are used to construct high-resolution correlation among three overlapping Middle-Cambrian marine sedimentary sections. Successions studied are; 1) the Drumian Global boundary Stratotype Section and Point (GSSP) in the Drum Mountains, western Utah, 2) the Marjum Pass section in the House Range, western Utah, and 3) the Packrat section in Great Basin National Park, eastern Nevada. The HRE lithological variations follow broad facies patterns. Carbonates dominate at the edges of the HRE and decrease inward, while detrital materials dominate along the HRE trough and decrease outward. The carbonate/detrital ratio varies on the HRE ramps, the area between the HRE Edge and trough, due to; 1) the position of each section, (2) sea level fluctuations, and 3) the physical processes, primarily storms, that act on the carbonate platform. This ratio increases during sea level fall and storm events, and maximizes during the maximum sea level fall. It also decreases during sea level rise, and reaches its minimum at times when sea level is at a maximum stand. Careful examination of facies variations among the studied sections helps to decipher the depositional setting at each section. The GSSP is a shallow trough section, the

Marjum Pass is a lower slope section of the northern HRE ramp, and the Packrat is a lower slope section of the southern HRE ramp.

1.1. Introduction

The Middle-Cambrian HRE was formed by a normal fault that extended about 400 km in a NE-SW direction across what is known as the Great American Carbonate Bank (Hintze, 1988) (Figs. 1.1 and 1.2). The Great American Carbonate Bank is a Laurentian extensive carbonate continental shelf that is built up mainly from algal and/or microbial carbonate sediment (Palmer, 1971; Brady and Koepnick, 1979; Aitken, 1997) (Fig. 1.1). The fault bounds the southern margin of the asymmetric embayment separating the shallow-water carbonate sediment from deep-water, terrigenous-dominated sediment (Rees, 1986). The northern margin of this trough is a drowning platform that was formed as a southward sloping ramp (Rees, 1986). As the Laurentian landmass turned counterclockwise during the Phanerozoic, the normal fault rotated from the NW-SE to the NE-SW direction (Rees, 1986) (Figs. 1.1 and 1.2). In this paper, today's coordinates is used unless otherwise stated. Therefore, the easterly paleo-trade winds are referred to here as northerly trade winds. Although the Middle-Cambrian HRE was subjected to four compressional periods during the Paleozoic and Mesozoic, and extensional periods during the Cenozoic, that displaced and distorted its original configuration, the studied sections reported here lie in areas that have little deformation (Dickinson, 1981; Robison, 1982; Speed, 1982; Rees, 1984; 1986).

Many paleontological, sedimentological and stratigraphical studies have been done using multiple sections from within and outside the embayment (Palmer, 1965; Brady and Koepnick, 1979; Dickinson, 1981; Robison, 1982; Speed, 1982; Rees, 1986; Aitken, 1997; Elrick and Snider, 2002; Langenburg, 2003; Howley and Jiang,

2007; Brett et al., 2009; Halgedahl et al., 2009; Howley and Jiang, 2010). They rely on widely-spaced sampling and field observations to extract sea level fluctuations, tectonic evolution and depositional history of the HRE. Although they are useful in examining spatial and temporal long-term variations among sedimentary sequences, many key elements may be missed and misinterpreted, especially when high resolution is required. More challenges are added at the upper carbonate ramp, close to the carbonate platform, where varying carbonate production, sea level fluctuations, and physical processes produce rapidly changing lithologies. Identifying and tracing small-scale erosional surfaces, hiatuses, and minor thickness changes are key elements in distinguishing between normal deposition and storm deposits. Closely spaced sampling, along with field observations, are necessary to unravel some of these complexities. This study focuses on regional high-resolution correlation among three Middle Cambrian marine sedimentary sections that are located within the HRE and cover the interval through the base of the Drumian Stage. The sampled sections include; 1) the Global boundary Stratotype Section and Point (GSSP) for the Drumian Stage that has been placed on Stratotype Ridge in the Drum Mountains, western Utah, 2) the Marjum Pass section in the House Range, western Utah, and 3) the Packrat section in Great Basin National Park, along the southern flank of the Snake Range, eastern Nevada (Fig. 1.2). Both the GSSP and Marjum Pass sections have been previously studied and their depositional setting have been defined. The GSSP was introduced as a slope section while the Marjum Pass section was reported to be deposited at the deepest part of the HRE (Langenburg, 2003; Babcock et al., 2004; 2007; Howley, 2010; Howley and Jiang, 2010)

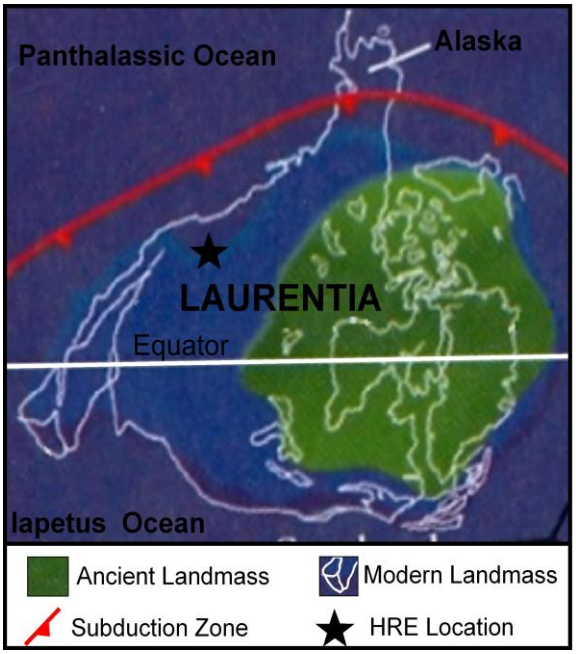

Figure 1.1. Paleogeographic map showing the Laurentian extensive carbonate shelf of the Middle Cambrian System. The approximate location of the House Range Embayment (HRE) is shown as a star (Scotese, 2001).

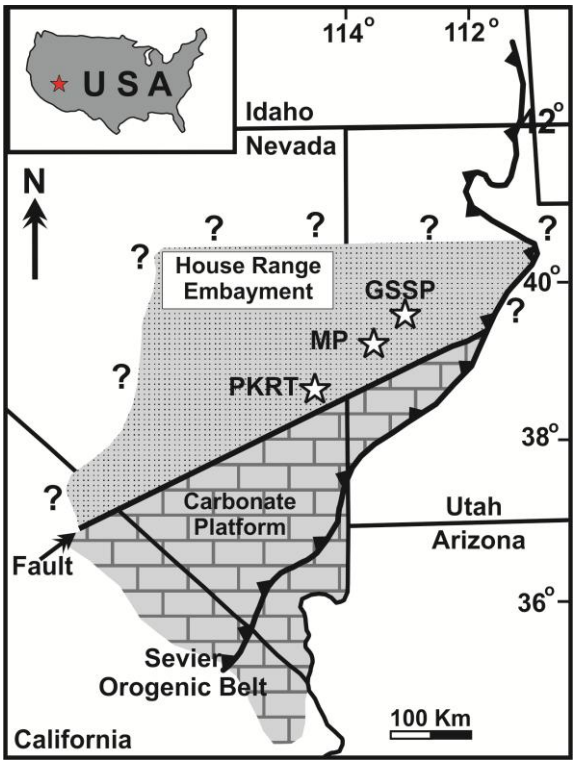

Figure 1.2. Non-palinspastic reconstruction map showing the location of the studied GSSP, Marjum Pass and Packrat sections (modified from Palmer, 1971; Elrick and Snider, 2002; Howley et al., 2006). As the Laurentian landmass turned counterclockwise during the Phanerozoic, the normal fault rotated 90° from the NW-SE to the NE-SW direction (Rees, 1986). The NE–SW normal fault separates the Laurentian carbonate shelf facies from the slope, with mixed siliciclastic-carbonate facies.

This paper is the product of research that had four goals. First, to investigate the complex lithological variations and their causes in the HRE. Second, to interpret climatic and sea level fluctuations that have caused the lithologic complexities. Third, to determine and refine the depositional setting represented by each section. Fourth, to identify, trace and interpret some of the numerous storm-event layers identified within the HRE.

1.2. Methods

1.5.1. Sampling and field observations

In the GSSP outcrop, minor structures including faults were observed on the Stratotype Ridge; the ridge that hosts the GSSP section. Therefore, the GSSP section was collected from the eastern flank of the Stratotype Ridge where three indurated limestone beds were traced ~130 meters away from the observed fault. The new location has better outcrop because the base of the Drumian Stage is well exposed, and no structures have been observed. In the Packrat section and nearby equivalent outcrops, syndepositional structures including folds, erosional surfaces, and debris flow are observed. A total of 1009 samples were collected from the three studied outcrops at 5 to 10 cm uniform intervals. All covered intervals were cleaned and brushed to the freshest surface possible. 20-30 gm of each sample were placed in small pre-labeled plastic zip-lock bags then grouped in larger cloth bags and returned to the Rock Magnetism Laboratory at LSU for final preparation and measurement. Each measurement is assumed to represent relatively short period of time. All samples were run for mass-specific magnetic susceptibility (χ) and carbonate percent ($CaCO_3$%). Because the facies within the HRE are mainly composed of varying ratios of carbonates and detrital materials, laboratory χ and $CaCO_3$% data are used to investigate and interpret lithologies. The three outcrops

were examined, in details, for structural complexities and lithologic variations. Syndepositional structures including folds, erosional surfaces, and density flows are also considered during the field work.

1.5.2. Mass specific magnetic susceptibility (χ)

Before measurement, all samples were crushed in order to reduce the effect of anisotropy on χ. Measurements were conducted using the Williams high-sensitivity χ Bridge in the rock magnetism laboratory at LSU; an extremely low, alternating field χ bridge that is calibrated relative to mass using standard salts (Swartzendruber, 1991). Ten grams of each sample were measured three times and the mean was calculated. Because it is very difficult to measure sample volume with high precision, mass-specific χ is generally considered the standard for magnetic susceptibility measurement (Ellwood et al., 2013). χ represents the bulk susceptibility of all minerals that are included in each sample (diamagnetic, paramagnetic and ferrimagnetic minerals (Nagata, 1961; Tarling and Hrouda, 1993). Because ferrimagnetic minerals are altered quickly after deposition in the marine environment (Karlin and Levi, 1983; Karlin and Levi, 1985) , and diamagnetic minerals have only weak, negative susceptibility, the χ signal in most marine sedimentary rocks comes mainly from paramagnetic minerals (Ellwood et al., 2013). Because detrital materials in the marine sediments are composed mainly of paramagnetic minerals (Ellwood et al., 2013), the χ variations account for the influx of these materials into the marine system and hence into the HRE. Laboratory measurements of χ are preferred over the field measurements in this study, because field measurements are affected by roughness of the measured surfaces, the surface area of the detector, the anisotropy of the outcrop, and the very low sensitivity of field instruments.

1.5.3. Percent carbonate ($CaCO_3$%) determined using carbonate digestion

Carbonate digestion has been performed using the method of Jones and Kaiteris (1983). 0.5 gm of each sample were crushed to a ~63μ size and dried for 1 hour at 110° C. 0.25 gm were carefully weighted and placed in the bottom of a reaction vessel, and 5 mm of 99% phosphoric acid was then placed in a side arm of the same vessel. The vessel was sealed and a vacuum produced within the vessel using a vacuum pump. The reaction was then initiated by tilting the reaction vessel, thus allowing the phosphoric acid in the vessel to mix with the sample. The reaction was allowed to continue for 1.5 hours, with agitation every 30 minutes. After the reaction ceased, the system was again pumped down and the pressure in the vessel measured before and after releasing the gas into the system. The difference between the two measurements represents the CO_2 gas pressure generated by the reaction. These results are calibrated for the volume difference between different reaction vessels as well as for both temperature, pressure before and after measurements (Jones and Kaiteris, 1983).

1.3. Results

$CaCO_3$% and χ data for the three sections are presented along with their normalized values in Figures 1.3 to 1.5. The raw data are presented as black dashed lines with all data points included, while the blue solid lines represent data smoothed using splines. The splined data for χ and $CaCO_3$% are normalized in order to better visualize the consistency between detrital/carbonate flux into the HRE. Splined data are preferred over the raw data in the normalization process, because much of the noise and high frequency cycles have been removed. In addition, as opposed to moving averages, splined data hold correct stratigraphic position for each data point. Normalized values are calculated for each data point using the following equation,

Norm. Value = (splined data point-MIN)/ (MAX-MIN), (1)

where MIN and MAX are the minimum and maximum values for the splined data set while MAX-MIN is the total range of the splined data. These curves start at the closest formation boundary associated with each section; the base of the Wheeler Formation for the GSSP and Marjum Pass sections, and the base of the Lincoln Peak Formation in the Packrat section. In order to better visualize all curves, χ is set to increase to the right, while the $CaCO_3$% is set to increase toward the left. These curves cover an interval that includes the Middle Cambrian uppermost part of the unnamed Stage Five and the lowermost part of the Drumian Stage. Twelve correlation points (CP), CP1 to CP12, and multiple arrows are added to both χ and $CaCO_3$% curves for correlation purposes (Figs. 1.6 and 1.7). The CPs highlight both peaks and troughs that have high correlation potential among the three sections examined, and the arrows mark the corresponding long-term trend of change. $CaCO_3$% is indicative of the amount of carbonate in each sample relative to the total mass of the sample. Non-carbonate percent is the inverse of $CaCO_3$%. Because χ variations represent detrital component; mainly the paramagnetic minerals that either flux into the marine system or result from diagenesis of the associated ferrimagnetic minerals after deposition in the marine environment (Nagata, 1961; Ellwood et al., 2000; Ellwood et al., 2006; Ellwood et al., 2013), non-carbonate diamagnetic materials can be extracted from the integration of χ and $CaCO_3$% curves (green area; Figs. 1.3, 1.4, and 1.5). These materials are likely to be either organic materials, quartz (sand/silt) or their mixture. Even though caution is required when interpreting this zone because χ is carried by wide spectrum of minerals that have wide χ range, such interpretation still valid through low χ intervals. In addition, its confidence increases if correlated among multiple equivalent sections.

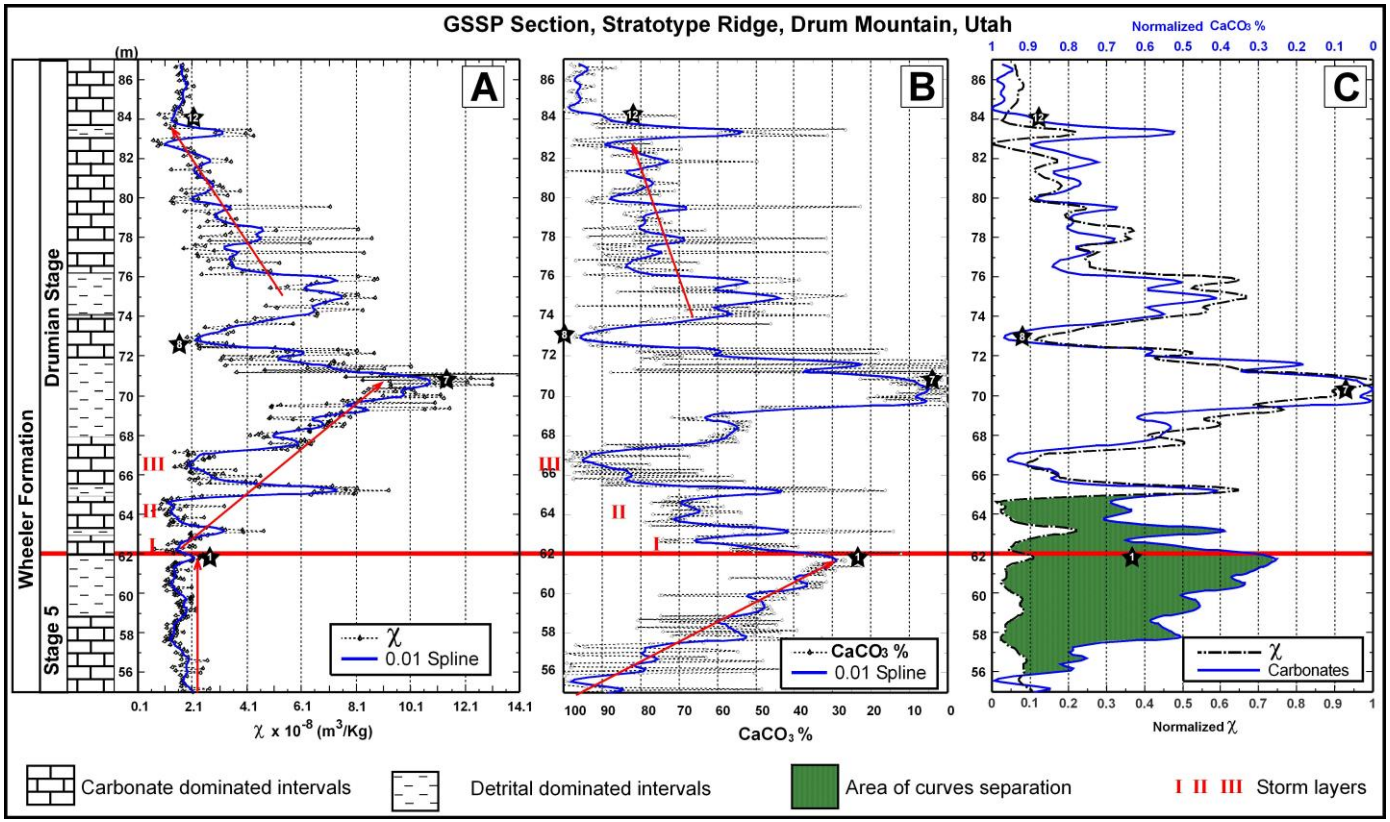

Figure 1.3. Three curves showing χ and $CaCO_3$% obtained for the GSSP section. A is the χ curve showing the raw χ data as a black dashed line with data points included, and smoothed data as a solid blue line. χ values increase to the right. B is the $CaCO_3$% curve showing $CaCO_3$% data as a black dashed line with data points included and smoothed data as a solid blue line. $CaCO_3$% values decrease to the right. C represents the normalized curves of χ and $CaCO_3$% plotted together. Only the smoothed data sets are normalized as noise and high frequency signal are removed. The direction of increase of χ and $CaCO_3$% are the same as in A and B. The base of the Drumian Stage is defined at 62 m (Babcock et al., 2007). The height for the GSSP is measured from the base of the Wheeler Formation. The numbered stars and red arrows in the A to C curves represent correlation points (CP1-CP12) and trends that are used for correlation purposes. Also the three events, I, II, and III, are high $CaCO_3$%, low χ, layers. The green coded interval represents an area where the $CaCO_3$% and χ curves are widely separated.

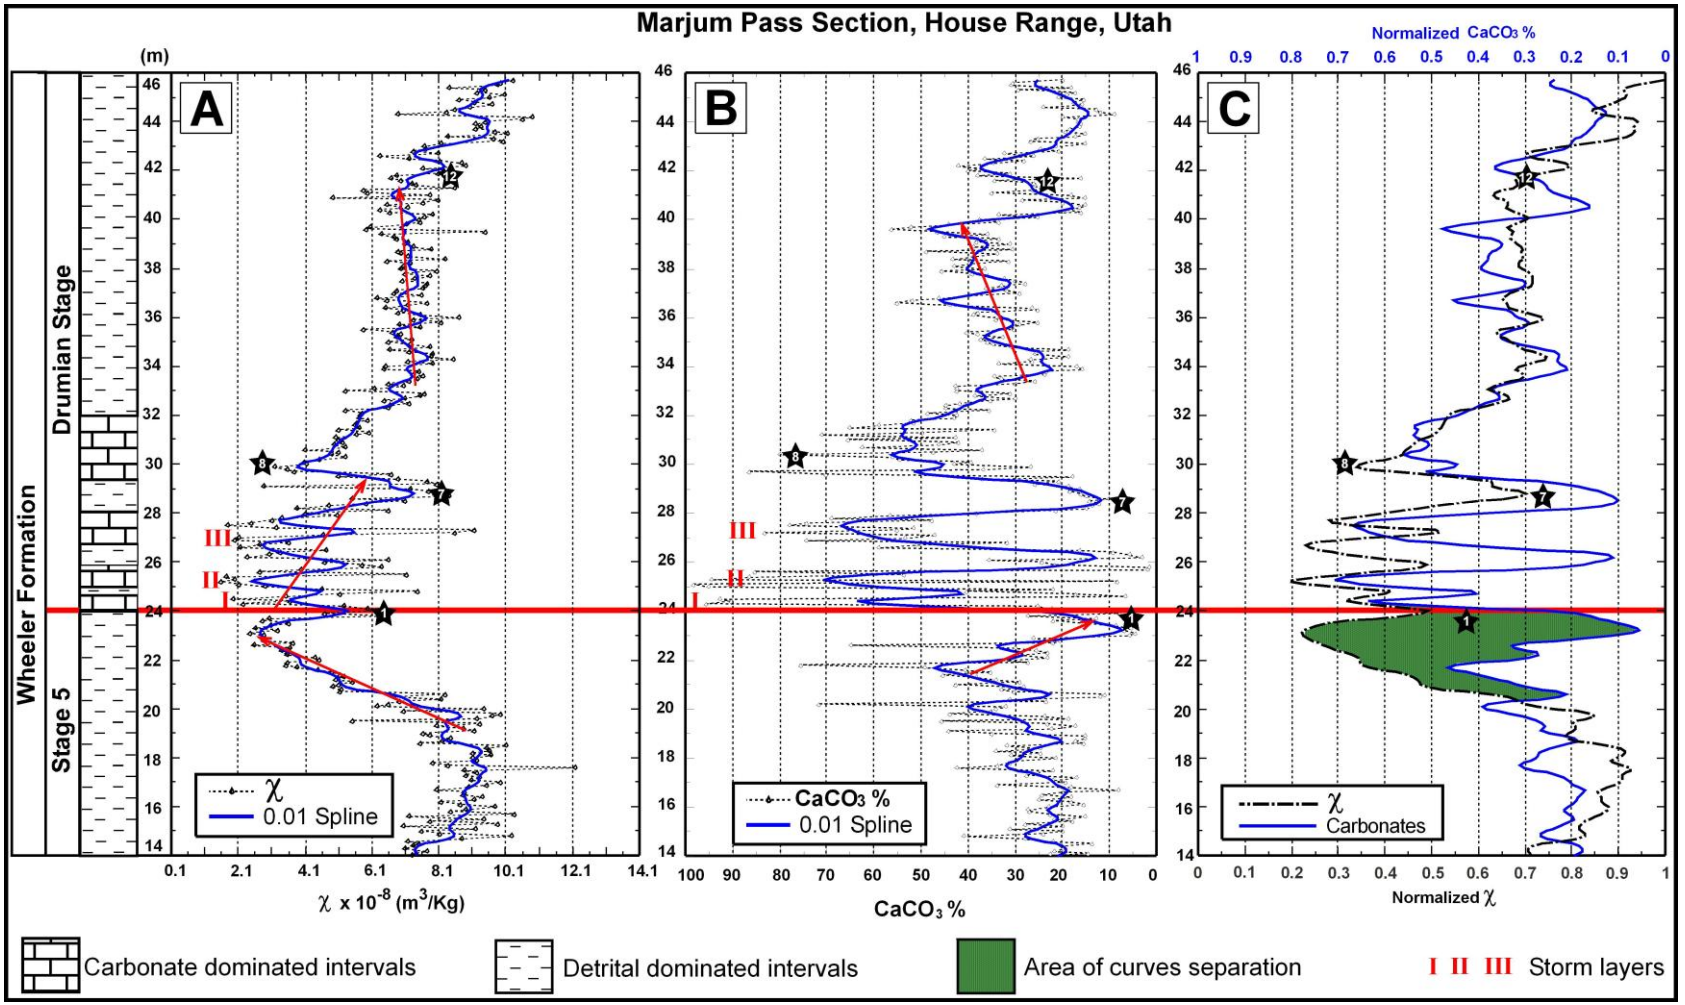

Figure 1.4. Three curves showing the results obtained from the Marjum Pass section. The features on the three curves, A to C, are illustrated in the caption of Figure 1.3. The base of Drumian Stage is defined at 24 m based on an ongoing research. Height for the Marjum Pass section is measured from the base of the Wheeler Formation.

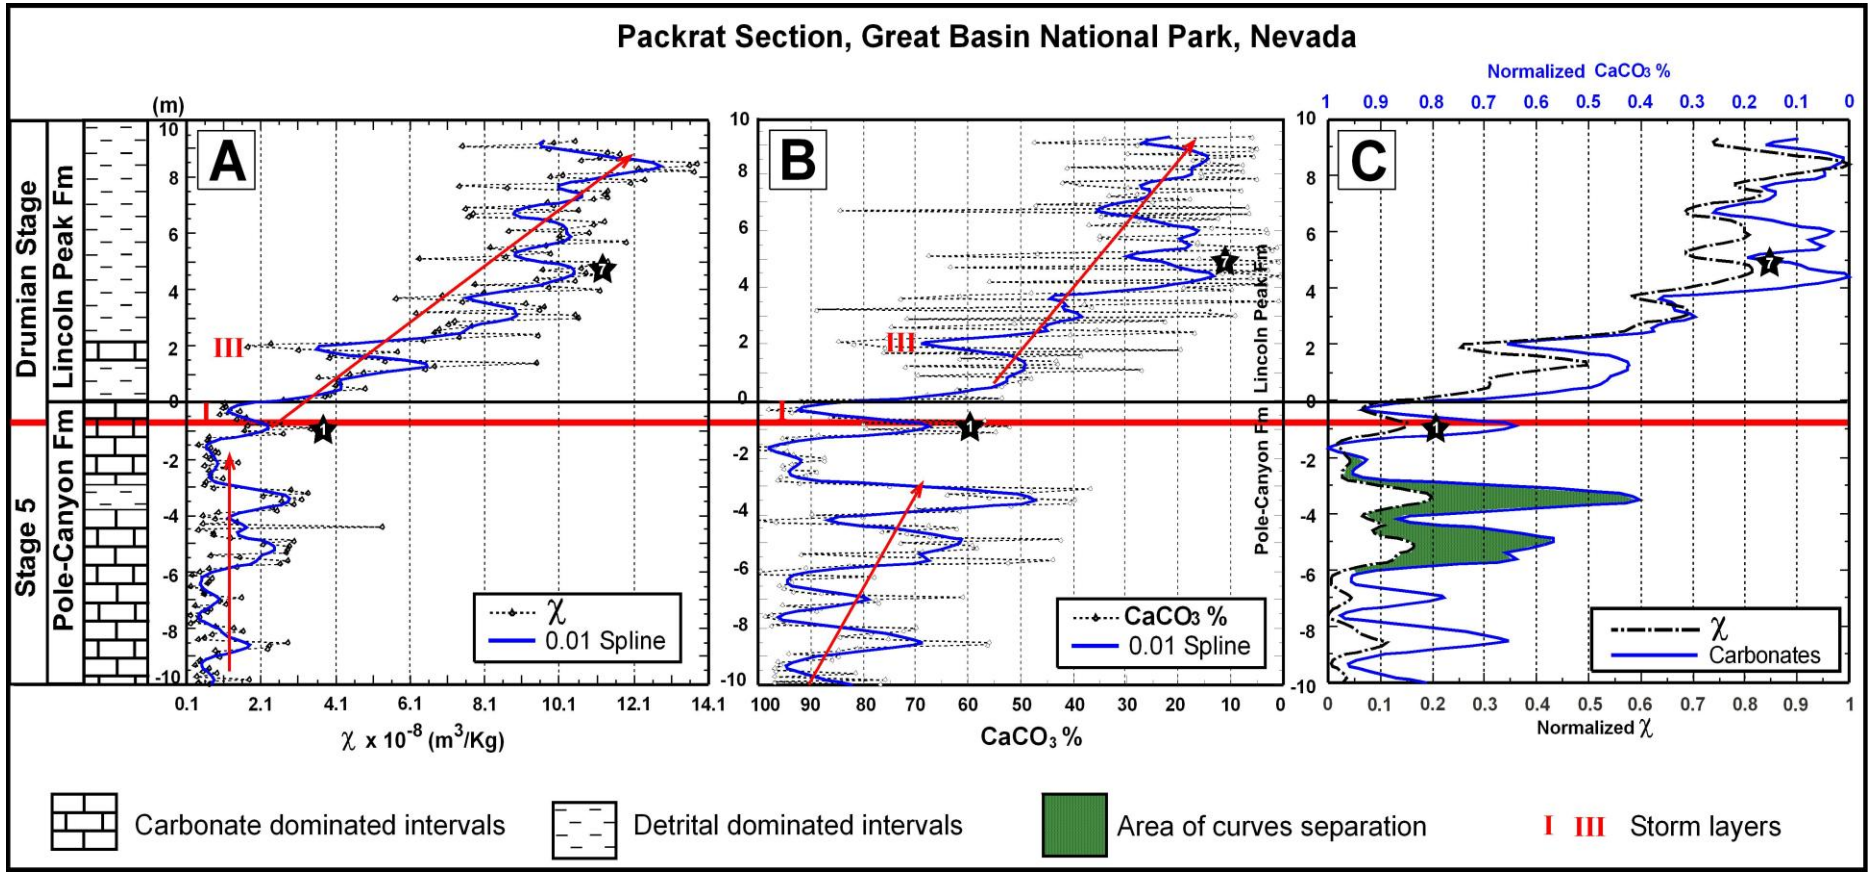

Figure 1.5. Three curves showing the results obtained from the Packrat section. The features on the three curves (A to C) are illustrated in the figure 1.3 caption. The base of Drumian Stage is defined here at ~0.8 m based on an ongoing research. Height for the Packrat section is measured from the base of the Lincoln Peak Formation.

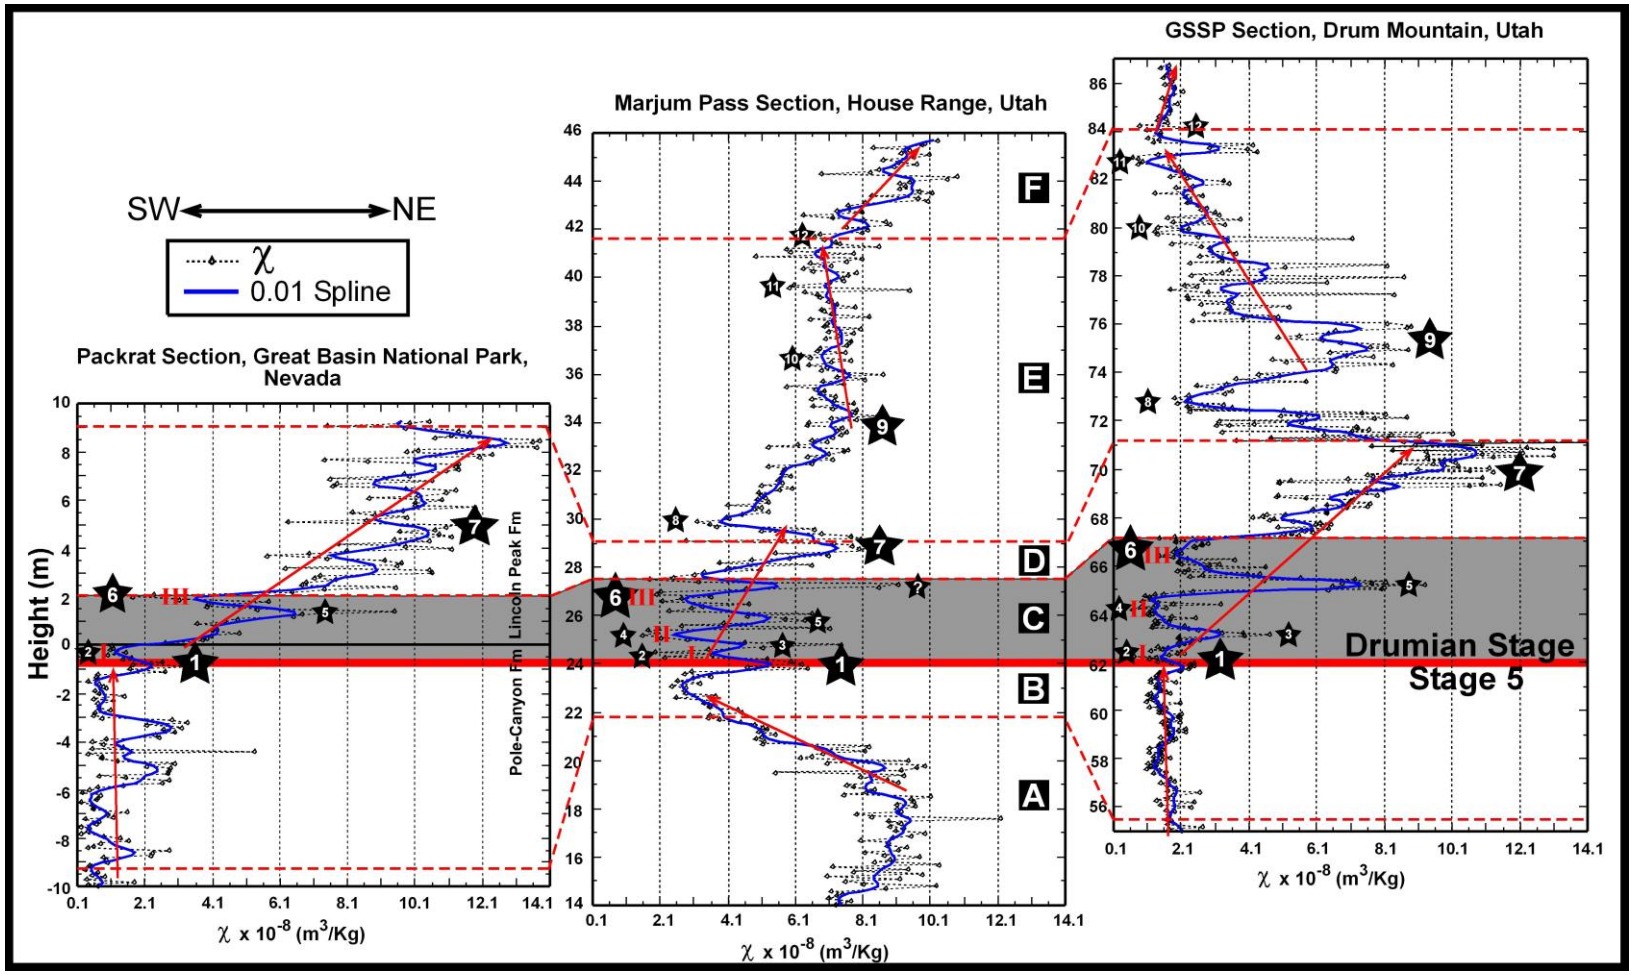

Figure 1.6. Three χ curves showing high resolution correlation among the studied localities; GSSP, Marjum Pass and Packrat Sections. The numbered stars represent correlation points (CPs) where the χ signal behaves the same among the three sections. Each CP represents either a peak or a trough on the χ curve. The six intervals, A to F, that are delimited by red dashed lines above and below the basal boundary of the Drumian Stage, have high correlation potential among the three sections. The red arrows represent the direction of change in the χ curve.

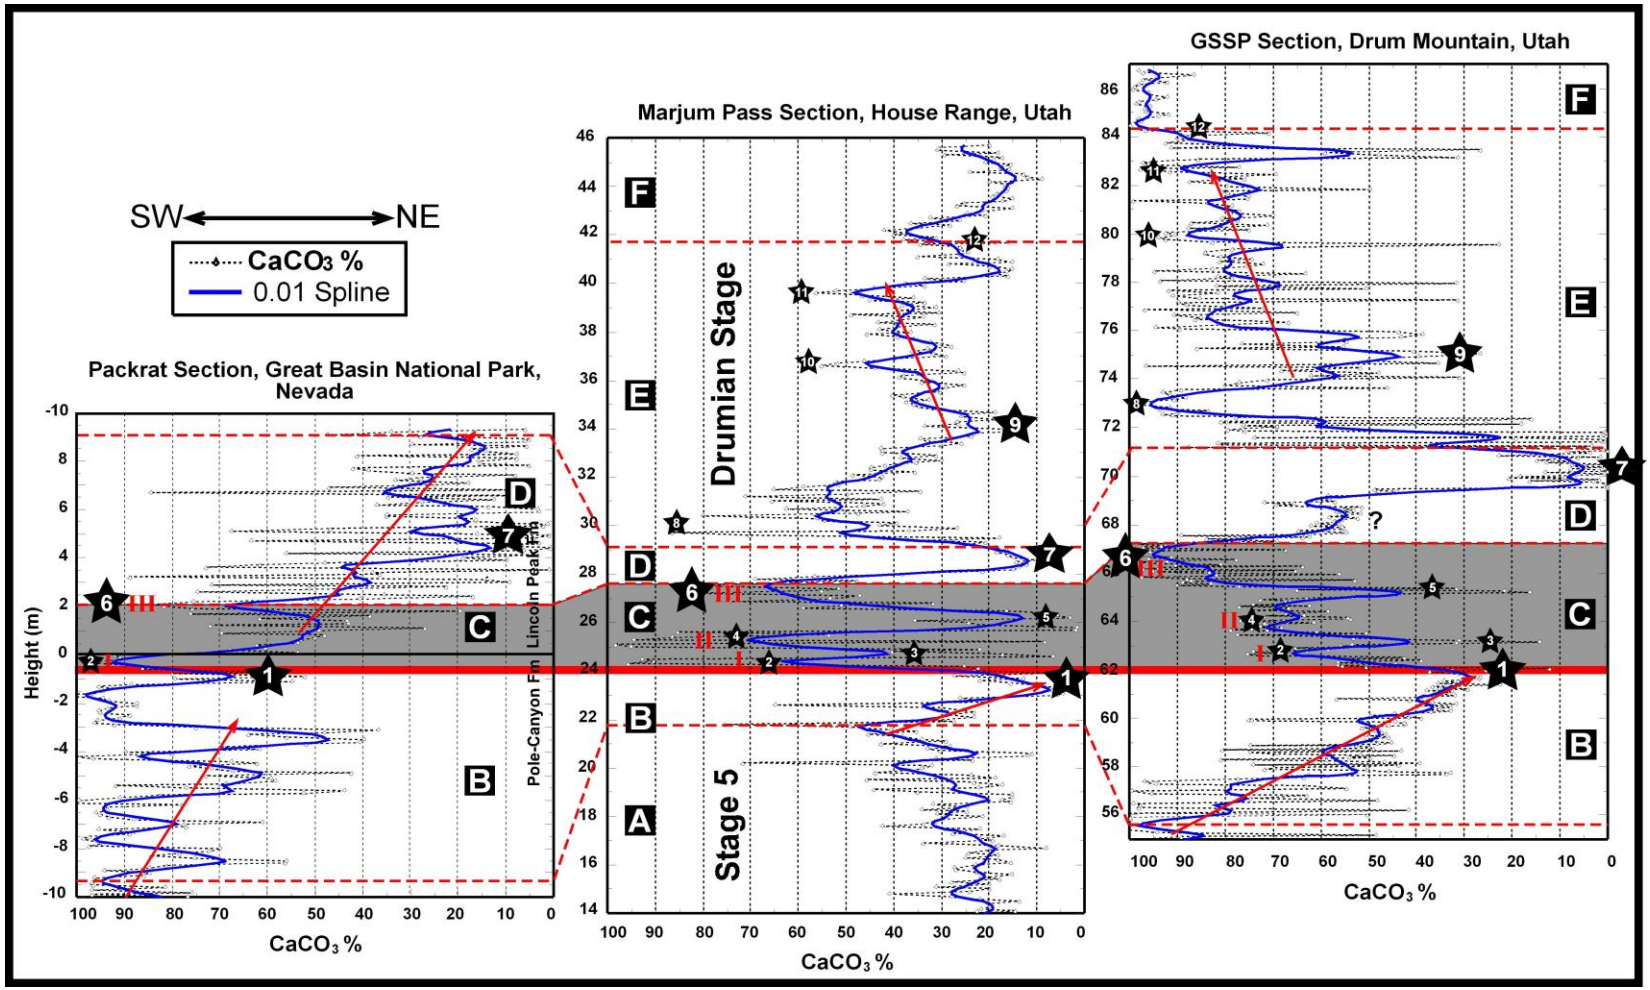

Figure 1.7. Three $CaCO_3$% curves showing high resolution correlation among the studied localities; GSSP, Marjum Pass and Packrat Sections. The numbered stars represent correlation points (CPs) where the $CaCO_3$% signal behaves the same among the three sections. Each CP represents either a peak or a trough on the $CaCO_3$% curve. The six intervals, A to F, that are delimited by red dashed lines above and below the basal boundary of the Drumian Stage, have high correlation potential among the three $CaCO_3$% curves. The red arrows represent the direction of change in the $CaCO_3$% curve.

At the GSSP section, the mean $CaCO_3$% value is ~62%, while the mean for χ is 3.66 x 10^{-8} m^3/kg (Fig. 1.3). In general, during Stage Five, χ values are generally low, ranging from 1.0 to 2.0 x 10^{-8} m^3/kg. The same low χ values are observed above the basal boundary in the Drumian GSSP section at 73 m and 84 m (CP8 and CP12; Fig. 1.3). Between these low values, the curve shows two long-term χ cycles. Above the base of the Drumian Stage, the first cycle exhibits a long-term χ increase up to 13.1 x 10^{-8} m^3/kg at 70.5 m, with the second cycle exhibiting a maximum at 75 m (~9.1 x 10^{-8} m^3/kg). Three low susceptibility intervals (I, II, and III) interrupt the long-term increase of the first cycle (Fig. 1.3). The carbonate curve shows a significant $CaCO_3$% increase from the first (I) to the third (III) interval. These intervals are separated by two χ highs or two $CaCO_3$% low zones (Fig. 1.3A and 1.3B). Figure 1.3C shows high consistency between χ and $CaCO_3$% normalized values, except for the lowermost interval where the $CaCO_3$% curve exhibits a monotonic, long-term decrease and the χ curve indicates very little change. This creates an area of separation in the two curves that increases in width toward the stage boundary. This separation area is color-coded (green) in this and the following diagrams (Figs. 1.3C, 1.4C, and 1.5C).

Stratigraphic timing indicates that the Marjum Pass section starts earlier and ends later than the lower and the upper limits of the GSSP section, respectively (Fig. 1.4). The mean $CaCO_3$% at Marjum Pass is ~33% while the mean χ is 6.7 x 10^{-8} m^3/kg. During Stage Five, the χ curve starts at a maximum value (~9.1x10^{-8} m^3/kg), but then decreases to very close to ~2.1x10^{-8} m^3/kg right below the base of Drumian Stage. The two cycles that are exhibited in the GSSP section are also identified in the Marjum Pass section as well. The upper and lower limits of these two cycles at the Marjum pass section are observed at 23, 30 and 42 meters above the base of

the Wheeler Formation (Fig. 1.4). The peaks of the two cycles remain slightly below 8.1x10^{-8} m^3/kg. A high frequency interval is observed above CP1 (24–30 m) and is correlated to the same interval in the GSSP section (CP1 to CP7) (Fig. 1.4). This interval includes three high carbonate pulses and shows an upward, long-term χ increase (Fig. 1.4A and 4B). Figure 1.1.4C shows high consistency between χ and $CaCO_3$% normalized values. Both χ and $CaCO_3$% decrease toward the basal boundary of Drumian Stage, again creating an area of separation, but one that is smaller than in its counterpart in the GSSP section (Fig. 1.4C).

The Packrat section covers most of the first cycle that has been observed in the other two sections (Fig. 1.5). The mean $CaCO_3$% of this section is ~59%, while the mean χ is 4.74 x 10^{-8} m^3/kg. During Stage Five, χ stays low, below the 2.1 x 10^{-8} m^3/kg gridline, with a few slight exceptions. Above the base of the Drumian Stage, χ shows a steady long-term increase up to ~13.5 x 10^{-8} m^3/kg (Fig. 1.5A). This behavior is correlative to the GSSP section, with the exception of the high-frequency interval and high $CaCO_3$% pulses that are absent in this section. Figure 1.5C shows the highest consistency between the χ and $CaCO_3$% normalized curves among the three sections. The normalized χ and $CaCO_3$% curves also separate below the Drumian Stage basal boundary (Figs. 1.3C, 1.4C, and 1.5C).

1.4. Correlation

Figures 1.6 and 1.7 represent χ and $CaCO_3$% correlation, respectively, among the three sections. In addition to the twelve correlation points, CP1 to CP12, that are traced partially from the GSSP through the Marjum Pass into the Packrat sections, six intervals, A to F, are also identified (Figs. 1.6 and 1.7). Each of these intervals has its own unique signal that can be traced along the NE-SW transect within HRE. Multiple arrows are placed in these figures on the χ and $CaCO_3$ curves

to highlight the long-term transgressive-regressive (T-R) cycles exhibited in these sections.

χ curves show high correlation potential above the CP7 between the GSSP and Marjum Pass sections. This interval represents ~1.5 cycles and includes CP8 to CP12. Correlation points CP1 through CP6 can be traced between the three sections (Fig. 1.6). This shaded interval is expanded in the GSSP section and more condensed at the Packrat section; the Marjum Pass section lies in between. Some of these correlation points (CP3, CP4, CP5 and CP6) are absent or have negligible thickness in the Packrat section (Fig. 1.6). CP7, on the other hand, shows a different thickness variation between the three sections, with highest thickness observed in the Packrat section, being thinnest in Marjum Pass section (Fig. 1.6). CP7 also has high correlation potential because, 1) its χ values start below 2.1 x 10^{-8} m^3/kg, 2) it peaks at the highest χ values in the GSSP and Packrat sections, but slightly below values in the Marjum Pass section, and 3) it is composed of ~5 short-term χ cycles in all sections. These cycles are represented as single data points in the Marjum Pass section because here it has condensed sedimentation at this level and because of its coarser sampling interval (10 cm). These short-term χ cycles are represented clearly in both the GSSP and Packrat sections (Fig. 1.6). Below CP1, the GSSP and the Packrat sections show high consistency with very little long-term χ change, while the Marjum Pass section shows a dramatic χ decrease.

The $CaCO_3$% highlights the three interruptive pulses (I, II, and III; Fig. 1.7). The correlation points CP2, CP4, and CP6 mark these pulses in the $CaCO_3$% curves. The $CaCO_3$% and thicknesses increase upward from the first (I) to the third (III) pulse. It is also observed that the thickness of each pulse decreases to the southwest until it vanishes (pulse II) or reduces markedly in its thickness (pulse III) in

the Packrat section (Fig. 1.7). Below CP1, $CaCO_3$% curves also highlight the overall decrease in $CaCO_3$% in the three sections, although χ curves through this interval show either no change or a χ decrease. Above CP7, there is high $CaCO_3$% correlation potential between the GSSP and the Marjum Pass sections.

1.5. Interpretation

Section location, sea level changes and physical processes that act on the carbonate platform contribute to how χ and the $CaCO_3$% signal behave in each section within the HRE. Eustatic, rather than relative, sea level changes are suggested here because the studied sections lie within an interval that is bounded by the second and third regional sequence boundaries, which are characterized by tectonic quiescence (Howley, 2010).

The normalized χ and $CaCO_3$% curves covary with each other during the studied interval in the three sections except for the interval below the base of Drumian Stage, where these parameters show an area of separation (Figs. 1.3C, 1.4C, and 1.5C). This area of separation decreases in size from the GSSP through the Marjum Pass to the Packrat sections, and marks the beginning of sea level rise. During this interval, $CaCO_3$% decreases in all sections, while χ records either decrease at the Marjum Pass section or very little change at both the GSSP and Packrat sections (Figs. 1.3C, 1.4C, and 1.5C). The non-carbonate materials seem to have less bulk susceptibility than expected, in contrast to the rest of the studied interval, suggesting the existence of non-carbonate diamagnetic materials such as organic matter and/or quartz grains at the beginning of the sea level rise. These materials could be the reason behind this area of separation as it may have dampened χ of the non-carbonate components. This indicates that χ signature is driven mainly by the non-carbonate materials within each sample. These

interpretation is in consistent with the work done by Ellwood and others (2000). They conclude that the paramagnetic and other detrital constituents mainly control the χ signal in marine sedimentary rocks.

The GSSP and Packrat sections have a more consistent χ signal and higher average $CaCO_3$% (~62% and ~59%) than the Marjum Pass section (~33%) (Figs. 1.6 and 1.7). This results from those sections being located closer to the carbonate platform than is the Marjum Pass section.

1.5.1. Drumian Stage GSSP Section

The GSSP section is close to the NE end of embayment trough where the embayment has minimal width and depth, in addition, the fault has minimal displacement compared with the Packrat section (Fig. 1.8). Therefore, the GSSP is surrounded by the carbonate platform, and is affected more than the other two sections by the advance and retreat of the carbonate factory. As the carbonate factory advances during sea level falls, the GSSP location is flooded with carbonates from the surrounding platform. The platform water currents that were driven by trade winds play an important role in delivering these carbonate sediments to the embayment. Laurentia was reported to straddle the equator during the middle Cambrian and was partly within the northerly trade winds belt during the Middle Cambrian (Scotese and Barrett, 1990; Elrick and Snider, 2002; Peng and Babcock, 2008; Howley, 2010). Therefore, the northern platform is likely to be the main source of carbonates into the HRE, with minor contribution from the southern platform during the time of maximum sea level fall.

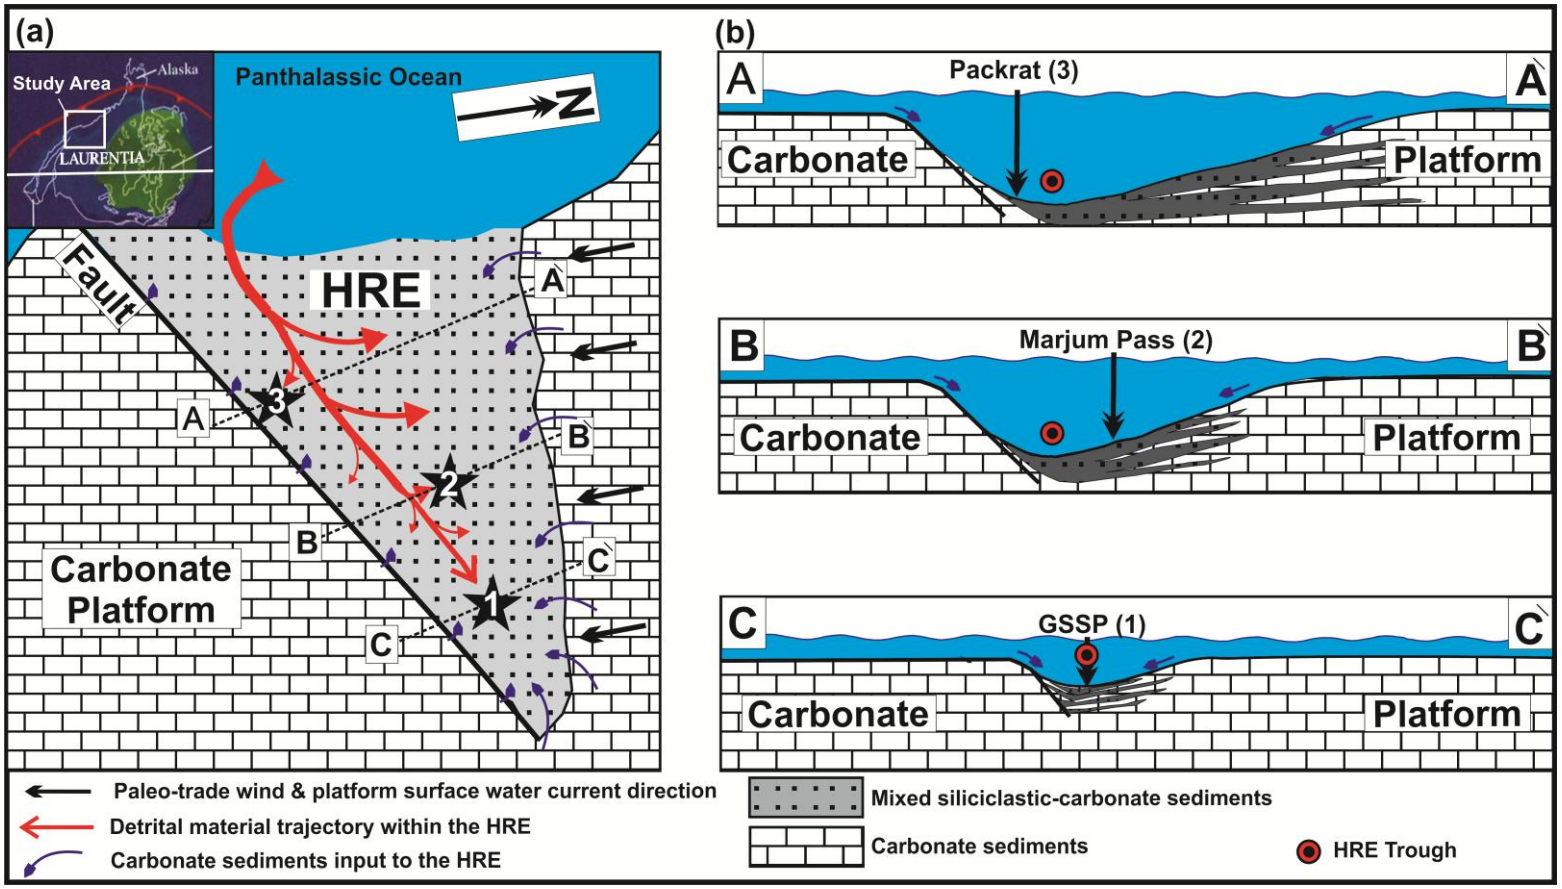

Figure 1.8. Hypothetical Paleogeographic map of the HRE showing facies distribution, sediment trajectories, and the location of the three sections relative to the embayment edge and trough. (a) A plan view of the embayment showing how detrital materials and carbonate are delivered to the embayment. Detrital materials are channelized first through the trough (the main red line) and spread to the northern and southern ramps (red arrows that split away from the main red line). Blue arrows around the embayment show that the carbonate dominated sediments have been delivered to the HRE across its edges. The present North direction and the direction of both paleo-trade winds and the platform surface currents are shown on the map. (b) Three cross sections showing the relative depth and width of the HRE at each section. Also shown is the location of each section relative to the embayment edge and trough.

1.5.2. Marjum Pass Section

The Marjum Pass section is located on the downslope side of the northern ramp (Fig. 1.8), where it is far from the embayment edge and thus receiving less carbonates than the other two sections. It has ~40% $CaCO_3$% during maximum sea level fall (at 22 m; Fig. 1.7) when the other two sections have more than 90% carbonates at the same time (Fig. 1.7). $CaCO_3$% analysis indicates that the Marjum Pass section was closer to the trough than to the northern edge of the HRE because it received more detrital material than carbonates (Fig. 1.7). The detrital materials are provided to the Marjum Pass section from the HRE mouth through the HRE trough, and its carbonates from either the northern carbonate platform during storm events or as pelagic carbonates. The gradual change in the upper and lower parts of the χ curve records gradual lithological variations while the middle part records frequent lithological changes (Fig. 1.6).

1.5.3. Packrat Section

The Packrat section lies on the southern ramp very close to the normal fault (Fig. 1.8) where carbonates are shed off the southern platform across the fault scarp to the section during the maximum sea level fall and early sea level rise. Accordingly, the southern platform is the main source of carbonates into the Packrat section because it is not likely that these carbonates cross the northern ramp and the trough to the section. Likewise, the Packrat section is closer to the southwest part of the HRE (Figs. 1.2 and 1.8), where the depth and width of the embayment and the fault displacement are at their maximum, producing more space to accommodate the north-coming carbonate sediments on the northern ramp. Syndepositional sliding, gliding and folding structures (Figs. 1.9 and 1.10), at or close to the section, indicate

that it is seated on the high angle surface of the southern ramp. Syndepositional folding suggests that it is a downslope section, close to the embayment trough.

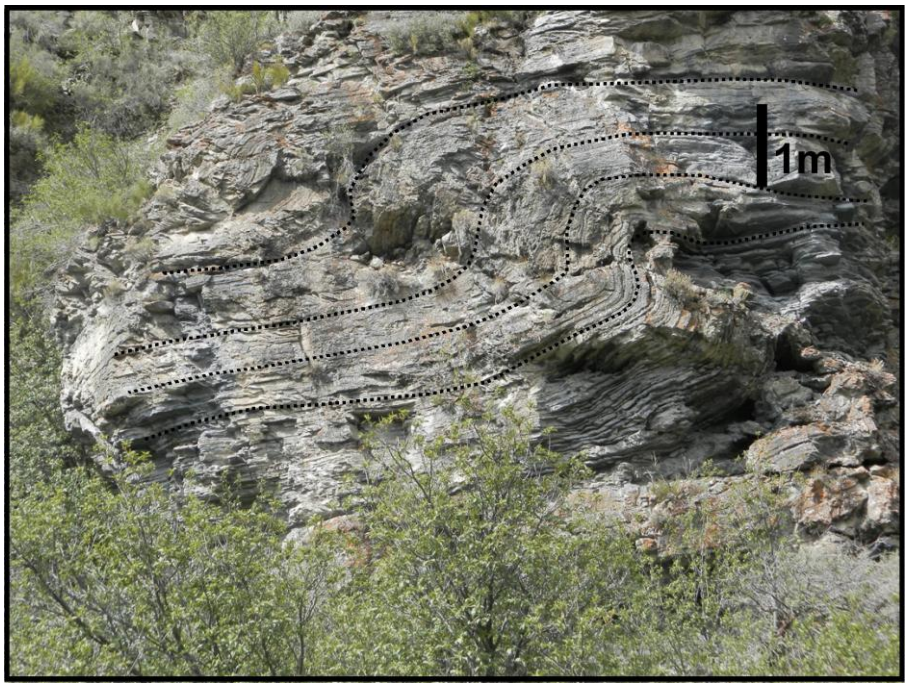

Figure 1.9. Photographs showing a syndepositional fold close to the Packrat section. The black bar represent ~1 meter scale.

Figure 1.10. Photographs showing a syndepositional density flow structure in the lower part of the Packrat section. The thickness of this layer varies with an average of ~0.5 m. The arrow indicates a boulder that was picked up by this downslope density flow and encased in the middle of this layer.

1.5.4. Integration of Sections and Facies Interpretation

Below CP1 (Fig. 1.7), both the GSSP and the Packrat sections represent the last phase of sea level fall, where $CaCO_3$% is at its maximum (>90%) at the boundary between intervals A and B (Fig. 1.7), and the earlier stage of sea level rise, where the $CaCO_3$% signal decreases (interval B; Fig. 1.7). The Marjum pass section covers the same interval (B), in addition to, the late stage of the preceding sea level rise and the entire sea level fall (Interval A; Figs. 1.6 and 1.7). The late stage of sea level rise is represented at the base of the Marjum Pass section where the $CaCO_3$% is at its minimum (~20%). During interval A, the sea level fall is characterized by increasing $CaCO_3$% values, while χ decreases during this time (Figs. 1.6 and 1.7).

Sea level continues to rise above CP1, leaving all sections at greater depths. Therefore, χ signal increases at the expense of $CaCO_3$% signal until maximize at CP7 (Fig. 1.6) reflecting the increase in terrigenous materials deposited during intervals B, C and D (Figs. 1.6 and 1.7). Three carbonate layers (CP2, CP4, and CP6) interrupt this long-term increase. These layers are interpreted as three separate storm events (I, II, and III) that eroded the surrounding carbonate platform and deposited their sediment within the slope and basinal area of the HRE (Fig. 1.8). This interpretation is supported by multiple observations; 1) the $CaCO_3$% of each storm layer is higher than its bounding layers and is well correlated among the studied sections. Also the shaded interval, C, that encompasses the three storm layers has higher $CaCO_3$% than its bounding B and D intervals, 2) the storm layers are observed during sea level rise where $CaCO_3$% is expected to decrease and χ is expected to increase, 3) they interrupt the long-term χ increase that maximizes at CP7 and accounts for detrital material increase above the base of the Drumian Stage (Fig. 1.6). They also interrupt the long-term $CaCO_3$% decrease that starts at

the base of interval B and minimizes at CP7 at the GSSP and Packrat sections (Fig. 1.7). 4) χ curve exhibits an overall smooth transition from high to low χ values, and vice versa, in the Marjum Pass section except for the interval across these storm deposits where high frequency χ signal is observed. This interval has the highest amplitude and frequency $CaCO_3$% signal in the Marjum Pass section reflecting high facies variation (Figs. 1.6 and 1.7), 5) the thickness of each storm layer decreases basinward, away from the carbonate platform and the HRE edge. Their thicknesses decrease from the GSSP section, shallow trough section, through the Marjum pass section, the lower slope section of the northern ramp, to the Packrat section, the lower slope section of the southern ramp (Fig. 1.8), and 6) an erosional surface is observed at the base of the first storm layer at the GSSP section (Fig. 1.11). This surface is located at 62 m above the base of the Wheeler formation and was recorded as a stage boundary (Babcock et al., 2004; Babcock et al., 2007; Brett et al., 2009). These storm layers were left undisturbed because bioturbation remained insignificant during the middle Cambrian (Gingras and Konhauser, 2015). In addition, it was reported that bioturbation was suppressed during multiple intervals in the Middle-Cambrian Wheeler Formation because the HRE is reported to have anoxic poorly-oxygenated deep water where the Oxygen Minimum Zone (OMZ) was well developed (Rogers, 1984; Rees, 1986; Savrda and Bottjer, 1987; Elrick and Snider, 2002; Gaines and Droser, 2003; Gaines and Droser, 2005; Gaines et al., 2005; Halgedahl et al., 2009). In the GSSP section, these storm events may be confused with normal deposition, even at high resolution sampling, because the $CaCO_3$% has higher variations and higher frequency through the whole section. Widely-spaced sampling and coarse correlation add more challenges in identifying these storm layers.

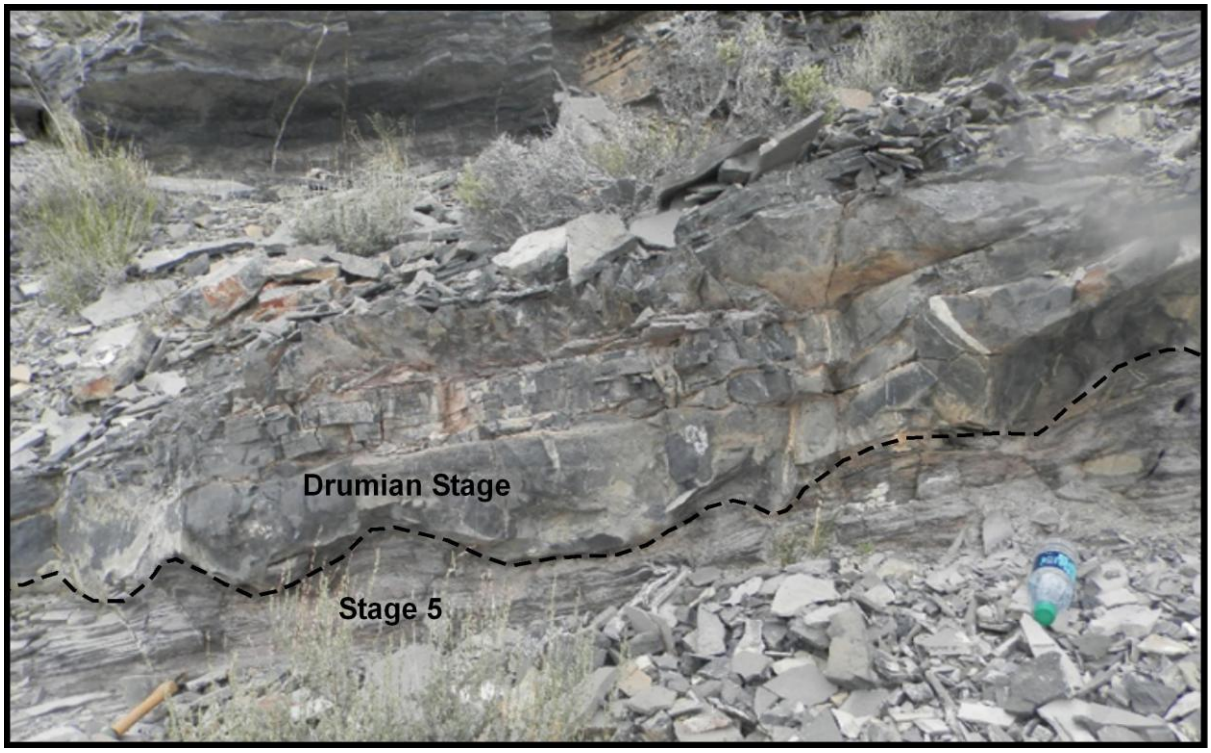

Figure 1.11. Photographs showing the basal boundary for the Drumian Stage at the GSSP section. Ripple marks predominate this erosional surface as it represents the base of the first storm layer (CP2) in Figure 1.7. Arrows indicate this erosional surface.

Multiple studies on the GSSP section refer to these interruptive storm layers as three calcisiltite layers that are composed of silt-size carbonate grains (Babcock et al., 2004; Babcock et al., 2007; Brett et al., 2009). Brett et al. (2009) interpret each calcisiltite bed as either a single storm deposit or a turbidity current event. This is in consistent with the interpretation presented here, where the three separate storm events eroded the carbonate platform, delivered the storm agitated sediments into the HRE slope and basinal areas, and triggered three separate turbidity currents. The studied interval lies within the Wheeler Formation that has been deposited in ramp-to-basin environment below the storm wave base (Robison, 1999; Babcock et al., 2004; Howley et al., 2006; 2007). Therefore, the turbidity currents traveled southward downslope the northern HRE ramp following the platform surface-water-currents that were driven mainly by the northerly trade winds. The turbidity currents are expected to be erosive in the upslope areas as it conserve its momentum close

to the northern HRE edge not too far below the storm wave base. They lost their inertia and exhausted downslope by settling of their suspended sediments along the ramp, and died out at or very close to the HRE trough. In addition, the low slope angle of the northern HRE ramp (<1° Palmer, 1971; Elrick and Snider, 2002) precluded such currents from maintaining their inertia under their own gravity. Field observations as well as χ and $CaCO_3$% curves support this interpretation. An erosional surface is observed at the base of the first storm layer in the shallow GSSP section that is close to the carbonate platform and the HRE edge. Unfortunately, the base of the second (II) and third (III) storm layers are not well exposed in the GSSP section. Also, the thickness of each storm layer decreases downslope because most of storm sediments were deposited in the upslope areas close to the northern edge (Figs. 1.6 and 1.7). Moreover, the coarse sediments, calcisiltite, has been reported in the shallow HRE GSSP section (Babcock et al., 2007; Brett et al., 2009), while finer sediments are observed in the lower slope Marjum Pass section.

The storm events cause disturbances along the southern edge of the embayment at the fault scarp, initiating some turbidity currents. Although the southern ramp has a higher slope angle than the northern one, the storm events have negligible thickness (event III) or are absent (event II), because the trade-wind driven surface currents move the storm sediments southward away from the HRE (Figs. 1.1 and 1.8). Also, the location of the Packrat section, being at the bottom of the southern ramp, makes it difficult for such turbidity currents to reach that location. Only the first event (I) is observed because the first storm event succeeded in moving the unstable deposits down the southern ramp and across the fault scarp.

Even though the GSSP and Packrat sections are closer to the embayment edge, than is the Marjum Pass section (Fig. 1.8), $CaCO_3$% is reduced more

dramatically at the GSSP (0-5%) and Packrat (~5%) sections than at Marjum Pass (10-20%) during the interval of maximum sea level stand (interval D; Fig. 1.7). In addition, detrital materials increased more dramatically in the GSSP (χ >12.1 x 10^{-8} m^3/kg) and the Packrat (χ ~13.1 x 10^{-8} m^3/kg) sections than in Marjum Pass (χ ~8.1x10^{-8} m^3/kg) at this time (interval D; Fig. 1.6). Moreover, the Packrat section is more expanded than the GSSP, and the Marjum Pass is the most condensed during this interval (Figs. 1.6 and 1.7). This dictates the source and the trajectory of detrital materials within the HRE. The detrital materials are provided to the embayment through the HRE mouth, where it connects to the deep open water of the Middle Cambrian Panthalassic Ocean (Fig. 1.8). They are channelized, first through the trough, and then they spread out to the northern and southern ramps of the HRE during sea level rise (Fig. 1.8). It is not likely that these terrigenous sediments were delivered to the embayment from the main continent by aeolian processes (Dalrymple et al., 1985), or through bypass zones that cut through the middle Cambrian extensive carbonate shelf (Hintze and Robison, 1975; Rogers, 1984; Rees, 1986), because the adjacent platform sections are composed of pure carbonates, in addition, the bypass zones are not recorded anywhere in Utah, southern Idaho or southern Nevada (Elrick and Snider, 2002). Therefore, it has been argued that terrigenous sediments were loaded into deep-water currents from far north (near the British Columbia–North-West Territories border) and brought into the HRE (Aitken, 1978; Aitken, 1997; Elrick and Snider, 2002).

Consequently, sections that are at or very close to the trough, and the HRE mouth, receive more detrital material at maximum sea level stand, than do those away from the trough, and the HRE mouth, on either the northern or the southern ramps (Fig. 1.8). These interpretations refine the position of each section; the GSSP

section is at the NE end of the embayment trough, the Marjum Pass section is on the downslope side of the northern ramp, far enough from the trough to receive less terrigenous materials than the other two sections, and the Packrat section is on the southern ramp close to the trough (Fig. 1.8). Syndepositional structures including folds, erosional surfaces and debris flows at or close to the Packrat section refine its position (Figs. 1.9 and 1.10). In summary, the GSSP and the Packrat sections are closer to both the embayment edge and trough, than is the Marjum Pass section because the latter was located on wide, gently sloping, northern ramp (Fig. 1.8). The approximate slope angle of the ramp is <1^{o} (Palmer, 1971; Elrick and Snider, 2002). Therefore, they have higher facies variations than is the Marjum Pass section. During maximum sea level fall, at the base of the interval B, the advance of the carbonate factory flooded the two sections reflecting >90% of $CaCO_3$% (Figs. 1.6 and 1.7). During maximum sea level rise, at CP7, they have enough accommodation space not only to accommodate the existing sediments but also to accommodate more sediments as the carbonate factory retreats, thus recording the lowest $CaCO_3$% and the highest terrigenous materials input in both sections at CP7 (Figs. 1.6 and 1.7). In contrast, the Marjum Pass section exhibit a smooth transition where a balance between the carbonate and detrital input is achieved. The only exception for the smooth transition occurs during the storm interval where high amplitude and high frequency facies variation are observed (Interval C; Figs. 1.6 and 1.7).

Above the CP7, both the GSSP and Marjum Pass sections have high correlation potential during intervals E and F (Figs. 1.6 and 1.7). These intervals represent deposition under normal circumstances where no storm events are observed. The eustatic sea level fluctuations drive the carbonate factory advance and retreat and account for the associated facies variation. The position of each

section relative to the embayment edges and trough, accounts for the difference in terrigenous (χ) and $CaCO_3$% at any location on those curves. CP12 records the maximum sea level fall where the $CaCO_3$% is a maximum at the GSSP, resembling the starting point of the section. Also CP12 marks the beginning of a sea level rise where χ curves show the start of the next cycle.

1.6. Discussion

Sediments in the HRE were delivered either under normal conditions, where deposition was controlled mainly by eustatic sea level changes, or under storm events, where deposition was controlled by the physical processes that act on the carbonate platform. According to the results obtained in this study, the location of each studied section, relative to the embayment edge and trough (Fig. 1.8), accounts for the differences in both χ and $CaCO_3$% signals between the three sections. The GSSP is a shallow trough section that is located at the very NE end of the HRE (Fig. 1.8) where it is surrounded mostly by the carbonate platform. Therefore, it was most heavily affected by the carbonate factory advance and retreat. It was flooded by carbonates during sea level fall and by detrital material during maximum sea level rise (CP7). The Packrat is a lowerslope section along the southern ramp where the seafloor had a higher slope angle than did the northern ramp. Therefore, syndepositional fold structures and debris flows are observed (Figs. 1.9 and 1.10) at or very close to the section. Carbonates were shed off the fault scarp, resulting in a carbonate-dominated interval during maximum sea level fall or early sea level rise. It was quickly replaced by a detrital-dominated interval, either during sea level rise or at the maximum sea level rise, because the Packrat section is a downslope section that is close to the HRE trough. The section at Marjum Pass is a downslope section on the northern ramp where an input balance of both carbonate and detrital materials

is recorded. Therefore, both χ and $CaCO_3$% have smooth transitions from high to low values and vice versa. This makes the Marjum Pass ideal for identifying eustatic sea level changes, because these data sets respond smoothly to lithologic variations.

Physical processes that act on the shelf have their own signal that are superimposed on the overall χ and $CaCO_3$% signals. CP2, CP4 and CP6 are three storm layers that were deposited from three separate turbidity currents, which, in turn, are controlled by three separate storm events (I, II, and III). They have high $CaCO_3$% (> 70%) that increase upward from the first to the third storm event layers in both the GSSP and Marjum Pass sections. The thickness of each layer decreases laterally toward the HRE trough because the turbidity current is gradually exhausted by settling of suspended load (Figs. 1.6 and 1.7). The thicknesses, and both $CaCO_3$% and χ signals variations of these storm layers result from the southwest width and depth increase of the HRE, and the location of each section relative to the embayment edge (Figs. 1.6, 1.7 and 1.10). The storm layers disappear or are minimized in thickness in the Packrat section, because of its location on the southern ramp close to the trough. In addition, the trade-winds driven water-currents drove the storm agitated sediments southward away from the embayment.

The source of terrigenous and carbonate materials were investigated using χ and $CaCO_3$% curves by observing the thicknesses and signal changes of the corresponding layers. This relationship is better observed during a time of maximum sea level rise and fall, where maximum terrigenous and carbonate influx into the HRE are best recovered. It is observed that carbonate-dominated intervals during maximum sea level fall or early sea level rise (interval B; Fig. 1.7) show an inverse relationship to that of terrigenous-dominated intervals during maximum sea level rise

(interval D; Fig. 1.6), when the location of each section is taken into account. The location of each section relative to the HRE edge is a key factor that helps in identifying the carbonate sediment source. Likewise, the location of each section relative to the HRE trough is a key factor that helps in identifying the terrigenous sediment source.

During Stage Five, carbonate layers in the shallow GSSP section, closer to the HRE edge, are expanded, while the deeper Marjum Pass section, farther from the embayment edge, has condensed carbonate layers (Fig. 1.6). The decrease in thickness of the carbonate-dominated intervals away from the HRE edge during maximum sea level fall and/or early sea level rise, is supported by the Packrat section. Although the Packrat section represents a deeper section, it exhibits an expanded section during Stage Five (interval B) because it was located closer to the HRE edge than was the Marjum Pass section. Consequently, the carbonate platform is considered as the main source of carbonate sediments into the HRE. More support for this interpretation is provided by the three storm layers, CP2, CP4, and CP6. The thickness of each layer decreases away from the HRE edge, from the GSSP to the Marjum Pass sections (Fig. 1.7).

During maximum sea level rise (interval D; Fig. 1.6), the Packrat section, on the SW side the HRE trough, has more expanded section than does the GSSP section, which is at the NE end of the trough. At maximum sea level rise, both sections had enough accommodation space to allow deposition of more sediment than already existed. The decrease of the terrigenous sediment in the NE direction, and away from the trough, is supported by observations at the Marjum Pass section. Although it was deposited in deeper water than the GSSP section, it is more condensed through the same intervals because it was farther from the trough than

the other two sections. This interpretation follows because the terrigenous sediment was being provided from the SW side of the embayment and channelized through the HRE trough to the GSSP section (Fig. 1.10). Some of this sediment settled in the trough and on the two ramps while on its way to the GSSP location.

The first, CP2, second, CP4, and third, CP6, storm layers can be traced from the GSSP through the Marjum Pass to the Packrat sections. These layers, then, represent chronostratigraphic markers that easily facilitate the correlation among the three studied sections and help in tracing important surfaces from one section into the other.

1.7. Conclusion

Even though the House Range Embayment (HRE) facies are composed of varying of carbonate/detrital ratios, the main lithological variations seem to follow broad facies patterns. Carbonate sediments are maximized at the HRE edges and decrease inward, and detrital materials are maximized along the HRE trough and decrease outward. In between these two end points, the carbonate/detrital ratio varies according to: 1) the position of each section within the HRE, 2) the eustatic sea level fluctuations during sediment deposition, and 3) the physical processes that act on the carbonate platform around the HRE. This carbonate/detrital ratio increases during sea level falls and storm events, and maximizes during times of maximum sea level fall. It also decreases during sea level rise, and minimizes during times of maximum sea level rise.

The Drumian Stage Global boundary Stratotype Section and Point (GSSP) in the Drum Mountains, Utah, is a shallow trough section that is located close to the northeast end of the HRE, and is surrounded by a western Laurentia carbonate platform. It is a carbonate-dominated section because the width and depth of the

HRE are at their minimum where the GSSP is located. Carbonates are shed off the surrounding carbonate platform to the GSSP locality. A second, coeval section, the Marjum Pass section in the House Range, Utah, is a lower-slope section found along the northern HRE ramp, where the width and depth of the HRE are higher than at the GSSP section. Marjum Pass is a detrital-dominated section that received its detrital components from the HRE mouth through the HRE trough, and its carbonates from either the northern carbonate platform during storm events or as pelagic carbonates. The Packrat section is a lower-slope section of the southern HRE ramp where the width and depth of the HRE were at their maximum. It is a mixed section; carbonate-dominated in its lower half and detrital dominated in its upper half. It received its carbonates from the southern portion of the carbonate platform and detrital materials from the HRE mouth through the HRE trough.

Physical processes that acted on the shelf had their own signal that are superimposed on the overall magnetic susceptibility (χ) and $CaCO_3$% signals. CP2, CP4 and CP6 are three storm-generated turbidite layers that were deposited from three separate turbidity currents, which, in turn, were controlled by three separate storm events (I, II, and III). They have high $CaCO_3$% (> 70%) that increases upward from the first to the third turbidite in both the GSSP and Marjum Pass sections. In addition, the thickness of each layer decreases laterally toward the HRE trough due to turbidity current exhausted. These three turbidite layers represent chronostratigraphic markers that make it possible to correlate among the three studied sections and help in tracing important surfaces from one section into the others.

CHAPTER II: TRACING THE BASE OF THE DRUMIAN STAGE: TESTING THE SYNCHRONICITY OF THE FAD/LOOP OF *PTYCHAGNOSTUS ATAVUS* WITHIN THE HOUSE RANGE EMBAYMENT, WESTERN LAURENTIA

The base of the Drumian Stage at the Global boundary Stratotype Section and Point (GSSP) locality in the Drum Mountains, Utah, was defined by the First Appearance Datum (FAD) of the Agnostoid trilobite *Ptychagnostus atavus* (Babcock et al., 2007). The Lowest Occurrence Observed Point (LOOP) of the same fossil was reported at 27 m above the base of the Wheeler Formation in the House Range, western Utah, and at 30 m above the Lincoln Peak/Pole Canyon formations boundary in the southern Snake Range, eastern Nevada (Robison, 1982). Speculation arises concerning the validity of the FAD/LOOP of *P. atavus* as biostratigraphic marker used to constrain the base of the Drumian Stage in these locations when high resolution correlation is conducted. Is it synchronous across the House Range Embayment (HRE)? If not, where is the base of Drumian Stage in the Marjum Pass locality, House Range and the southern Snake Range? Is *P. atavus* a useful index in defining the base of the Drumian Stage?

The answer to these questions becomes more difficult in the absence of common lithostratigraphic and other biostratigraphic markers across the HRE. This makes geochemical and geophysical data sets a more effective and reliable way to correlate among localities in western Laurentia. This study focuses on regional high-resolution correlation among three Middle Cambrian marine sedimentary successions that contain the base of the Drumian Stage. Closely-spaced samples have been collected from, (1) the Drumian GSSP in the Drum Mountains, western Utah, (2) the Marjum Pass section in the House Range, further west in Utah, and (3) the Packrat section in the Snake Range, Great Basin National Park, eastern Nevada.

The base of the Drumian Stage is traced from the GSSP to the other two successions and lies at the base of the first of three storm layers identified in all three studied successions. This layer represents a lithostratigraphic marker unit that helps to constrain not only the basal boundary of the Drumian Stage, but also the LOOP of *P. atavus* within the HRE slope and basinal sections studied. The FAD/LOOP of *P. atavus* is diachronous within the three studied sections and is recorded within carbonate-dominated storm deposits. However, its acme is synchronous and is observed at the base of the carbonate-dominated layer, CP8, which was deposited during normal sedimentation processes. Unfortunately, the GSSP was defined based on reworked *P. atavus* specimens at the base of the first storm layer that has an erosional base and is composed of reworked sediments. Consequently, the Drumian stage GSSP should be redefined. The Packrat section in Great Basin National Park is a good candidate for redefinition because it is the least affected by storm deposits above the Pole Canyon/Lincoln Peak formations boundary, has high sediment accumulation rates (SAR), and records sea level fluctuation effectively. The LOOP of *P. atavus* is likely to occur globally within carbonate-dominated facies. Facies are well correlated among slope-and-basinal successions of western Laurentia and southern China at the LOOP of *P. atavus*.

2.1. Introduction

The International Union of Geological Sciences (IUGS) and the International Commission on Stratigraphy (ICS) are working hard to locate stratigraphic sections that have continuous sedimentation with decent sediment accumulation rates (SAR) that assure events separation. Such successions represent formally defined standards for the Phanerozoic, and once all are defined, will serve as the Global boundary Stratotype Section and Point (GSSP) for the base of any given geologic

stage (Cowie, 1986; Cowie et al., 1986; Remane et al., 1996). The rules for defining GSSP sections indicate that a GSSP should not be defined based on a reworked species, not have any major erosional surfaces, not have missing intervals or reworked sediments at the GSSP level, because it represents a reference section to which other equivalent sequences can be correlated (Cowie, 1986; Cowie et al., 1986; Remane et al., 1996).

This study focuses on the GSSP for the basal boundary of the Middle-Cambrian Drumian Stage, at ~505 Ma (Gradstein et al., 2012). It was ratified in 2006 by both the ICS and IUGS, and placed at the First Appearance Datum (FAD) of *P. atavus* on Stratotype Ridge, Drum Mountains, Utah, USA (Babcock et al., 2007). The Drumian GSSP section was selected within an open-shelf to basinal low-latitude locality because it contains unique faunal assemblages that can be correlated to low and high latitude sections of both open-shelf and slope-to-basin areas (Babcock et al., 2004; 2007). *P. atavus* was favored to define the base of this stage because it has worldwide recognition and its FAD was correlated to Lowest Occurrence Observed Point (LOOP) among multiple localities; Australia, Asia, Europe and North America (Robison, 1982; Rowell et al., 1982; 1994; Geyer and Shergold, 2000; Peng and Robison, 2000; Ergaliev and Ergaliev, 2001; Pham, 2001; Babcock et al., 2004; Peng et al., 2004; 2007). In the present study, two other equivalent sections were targeted, (1) the Marjum Pass section that was collected in the House Range (39°14'30.13" N - 113°22'30.61" W) , western Utah, and (2) the Packrat section that was collected along the North Fork of the Big Wash (38°54’00.63926” N - 114°13’25.05219” W), Great Basin National Park, southern Snake Range, White Pine County, eastern Nevada (Fig. 2.1).

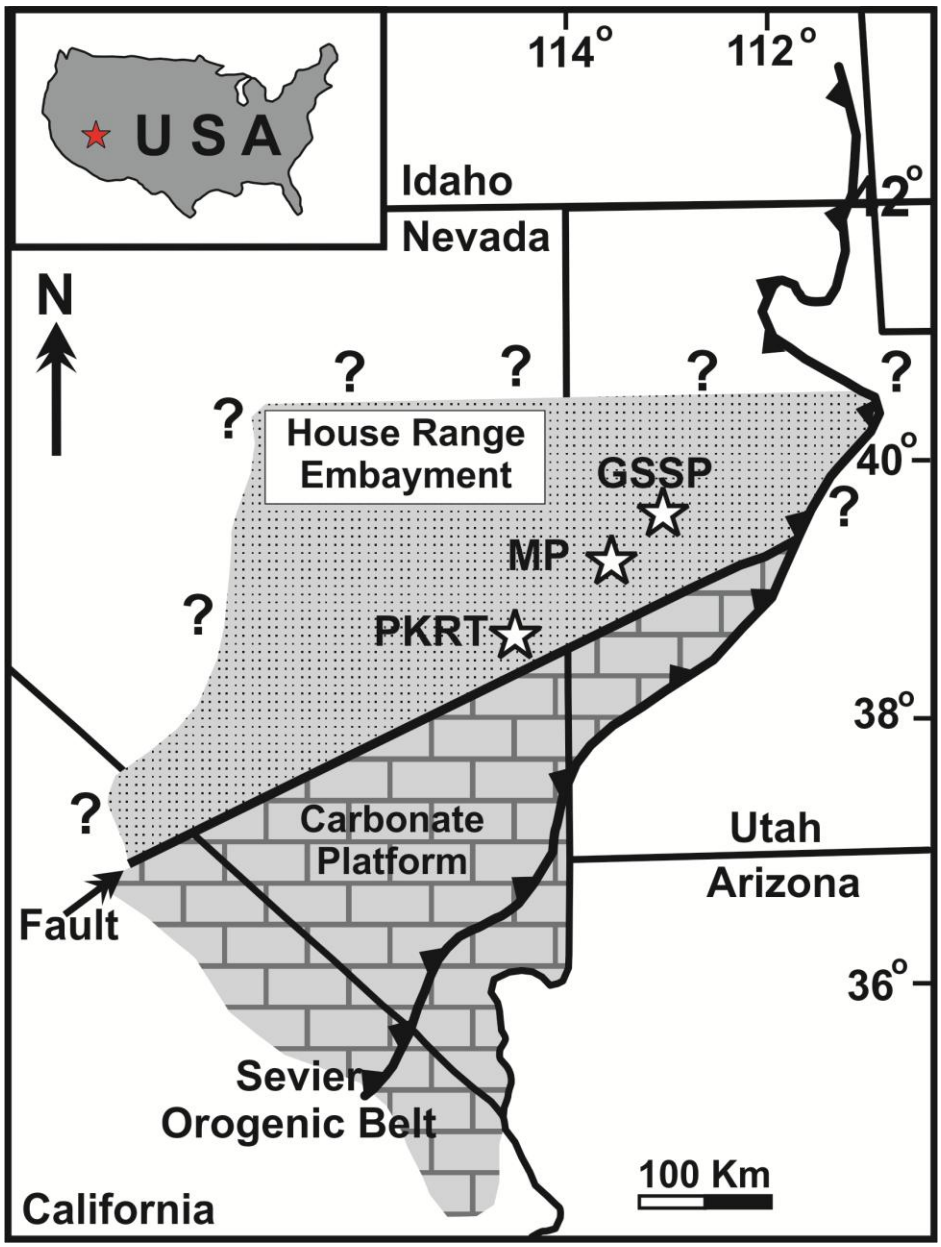

Figure 2.1. Non-palinspastic reconstruction map showing the location of the studied GSSP, Marjum Pass and Packrat sections (modified from Palmer, 1971; Elrick and Snider, 2002; Howley et al., 2006). The NE–SW normal fault separates the Laurentian carbonate shelf facies from the slope, mixed siliciclastic-carbonate facies.

The stratigraphic position of FAD of *P. atavus* in the HRE was defined at 71 m above the Wheeler Formation in the Drum Mountains, and the LOOPs of *P. atavus* at 27 m above the base of the same formation in the House Range, and at ~30 m above the base of the Lincoln Peak Formation in the Snake Range (Robison, 1982; Rowell et al., 1982; 1999). At the GSSP section, a few individuals were recovered after intensive *P. atavus* search below its previous stratigraphic position.

Accordingly, the FAD of *P. atavus* was stratigraphically moved down to 62 m above the base of the Wheeler Formation, at the base of the first calcisiltite, the first storm, layer (Babcock et al., 2004; 2007). However, the previous FAD of *P. atavus* is considered to be its acme because a thin coquina limestone bed that is composed almost entirely of *P. atavus* allochems was observed at the GSSP section (Babcock et al., 2007).

Testing the synchronicity of the FAD/LOOP of *P. atavus* within the HRE was challenging and its correlation among the three locations was tentative. Multiple factors led to this uncertainty. First, the FAD/LOOP positions in the three sections are not tied to lithostratigraphic nor other reliable biostratigraphic markers that can be traced from one section into another. Second, the three sections are markedly different in lithology: the GSSP is carbonate-dominated, Marjum Pass is detrital-dominated and the Packrat locality has multiple mixed facies (Chapter-I; Howley et al., 2006). Third, *P. atavus* has exhibits only rare occurrences and requires intensive search to be recovered. As a result, in the GSSP section, the FAD of *P. atavus* was redefined at 9 m below its previous position before it was finally ratified in 2006 (Robison, 1982; Babcock et al., 2004). Last, *P. atavus* is often confused with *Ptychagnostus gibbus* because these two Agnostoid trilobites have multiple common morphological characteristics (Robison, 1982; Rowell et al., 1982). The coarse correlation among HRE sections has contributed to the resolution problem discussed above. Although coarse correlation is useful in identifying long-term lithological variations that solve many other problems, still, it is limited in defining common chronostratigraphic surfaces to which these FAD/LOOP points can be adjusted.

The present study integrates the high-resolution correlation among the GSSP, Marjum Pass, and Packrat sections that has been established using Magnetic

susceptibility (χ) and calcium carbonate content ($CaCO_3$%), with the LOOP, FAD and acme of *P. atavus*. The search for *P. atavus* was also conducted at the Packrat and Marjum Pass sections. Our goals here were, 1) to identify lithostratigraphic marker (s) that might be used to trace the base of the Drumian Stage within the HRE, 2) to trace the FAD/LOOP of *P. atavus* from the GSSP through the Marjum Pass and into the Packrat section, 3) to test the synchronicity of *P. atavus* within the HRE, and 4) to investigate the reliability of *P. atavus* as biostratigraphic marker for high resolution studies.

2.2. Geological background

The House Range Embayment (HRE) was created by normal fault that cut through an extensive carbonate belt located along the western Laurentian continental margin and propagated eastward to ~400 km during the Middle Cambrian (Palmer, 1971; Brady and Koepnick, 1979; Rees, 1986; Hintze, 1988; Aitken, 1997) (Fig. 2.1). Therefore, the HRE represents a half-graben structure that is bounded by the normal fault to the south, and composed of a trough with northern, and southern ramps. The trough runs parallel with the fault propagation direction, and represents the deepest part of the embayment. The northern ramp is a drowning platform that was formed as a southward sloping ramp, and the southern ramp was a high-slope-angle ramp that has syndepositional structures such as syndepositional folding, sliding and density flows (Chapter-I; Dickinson, 1981; Robison, 1982; Speed, 1982; Rees, 1986). The HRE depth and width, as well as fault displacement, increase toward the HRE mouth, where the HRE meets the Panthalassic Ocean deep water along the western edge of the Laurentian passive margin (Rees, 1986). The Laurentian landmass was rotated 90° counterclockwise during the Phanerozoic, and the normal fault was turned from the NW-SE to the NE-SW direction (Rees, 1986). In

this paper, today's coordinates used unless otherwise stated. Therefore, the easterly paleo-trade winds are referred to here as northerly trade winds (Fig. 2.1).

Based on detailed facies examination, the precise depositional setting of each of the three studied sections within the HRE was reported (Chapter-I). The GSSP is a shallow trough section, the Marjum Pass is a lower-slope section of the northern HRE ramp, and the Packrat section is a lower-slope section of the southern HRE ramp. The water depth increased from the GSSP through the Marjum Pass to the Packrat sections, because the width and depth of the HRE increase in the southwesterly direction.

2.3. Methods

Unoriented samples were collected from the three sections at 5 to 10 cm intervals. During sampling, all covered intervals were cleaned and brushed to the freshest surface possible. 20-40 gm of each sample were placed in small (~76.2 x 76.2 mm) pre-labeled zip-lock plastic bags and returned to the Rock Magnetism Laboratory at LSU for final preparation and measurement. All samples were run for χ and $CaCO_3$% to account for detrital and carbonate contents respectively. χ measurements were conducted using the Williams high-sensitivity χ Bridge in the rock magnetism laboratory at LSU; an extremely low, alternating field χ bridge that is calibrated relative to mass using standard salts (Swartzendruber, 1991). Carbonate digestion has been performed using the method of Jones and Kaiteris (1983). Refer to chapter I for more details about mass-specific χ and $CaCO_3$% measurements. Each measurement is assumed to represent relatively short period of time. The outcrop search for *P. atavus* was conducted for the Packrat and Marjum Pass sections, and this included additional microscopic examination of 194 Packrat samples in the laboratory following sampling.

2.4. Results and Interpretations

$CaCO_3$% and χ data are presented versus the height of each section in figures 2.2 and 2.3. These curves cover an interval that includes the Middle-Cambrian uppermost part of unnamed Stage Five and the lowermost part of the Drumian Stage. The nine correlation star points (CPs: CP1-CP9), the red arrows, and the five intervals (A to E) are placed on the two figures for correlation purposes. They highlight the peaks and troughs, direction of change, and different sealevel stages represented by χ and $CaCO_3$ curves. Each of these features were traced from the GSSP through the Marjum Pass and into the Packrat section and reported to be synchronous across the NE-SE HRE transect (Chapter I). Similarly, the three storm layers (I, II, and III; Figs. 2.2 and 2.3) which are deposited during three separate storm events, are synchronous and traced among the three sections (Chapter I).

Because the base of the Drumian Stage was defined by the FAD of *P. atavus* (Babcock et al., 2007), the *P. atavus* search was conducted in the field and laboratory for both the Marjum pass and the Packrat sections. At the Packrat section, careful examination of the outcrop and the nearby scree using field lens, and laboratory microscopic examination of 194 samples, yielded no *P. atavus* specimens. In addition, multiple specimens have been recovered from the Marjum Pass section at ~30 m above the base of the Wheeler formation. This level lies within at the base of the carbonate dominated layer, CP8 (Figs. 2.2 and 2.3). The stratigraphic position of the acme, FAD/LOOP of *P. atavus* is presented as thick color-coded lines (red and green) in figures 2.2 and 2.3. This position is based of the work of Robison (1982), Rowell (1982), Babcock and others (2007), and the *P. atavus* search conducted here.

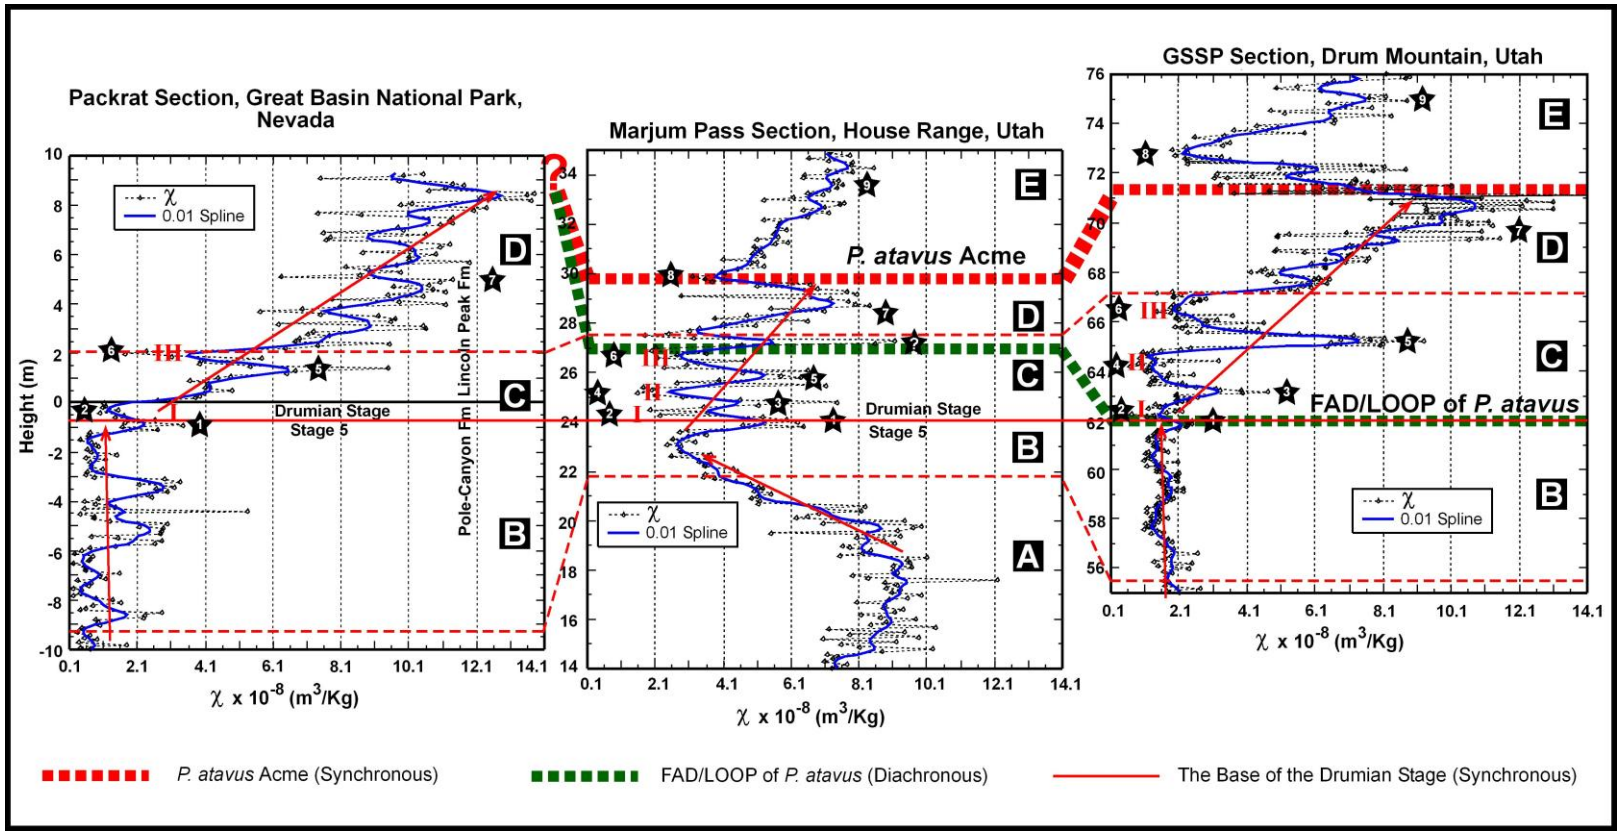

Figure 2.2. Three χ curves showing high-resolution correlation among the three studied sections(Modified from Chapter I). The height of these curves starts at the closest formation boundary; the base of the Wheeler Formation in the GSSP and Marjum Pass sections, and the base of the Lincoln Peak Formation in the Packrat section. The numbered stars represent correlation points (CPs) where the χ signal has high correlation potential among the three sections. Each CP represents either a peak or a trough on the χ curve. The base of the Drumian Stage was traced from the GSSP (Babcock et al., 2007) to the Packrat through the Marjum pass at the base of the first storm layer (CP2). The red dashed lines above and below the basal boundary of the Drumian Stage break the observed χ cycles into six intervals, A to E. The red arrows represent the direction of change of the χ curve. The stratigraphic position of the acme and the FAD/LOOP of *P. atavus* are presented as thick red and green dashed lines respectively**.**

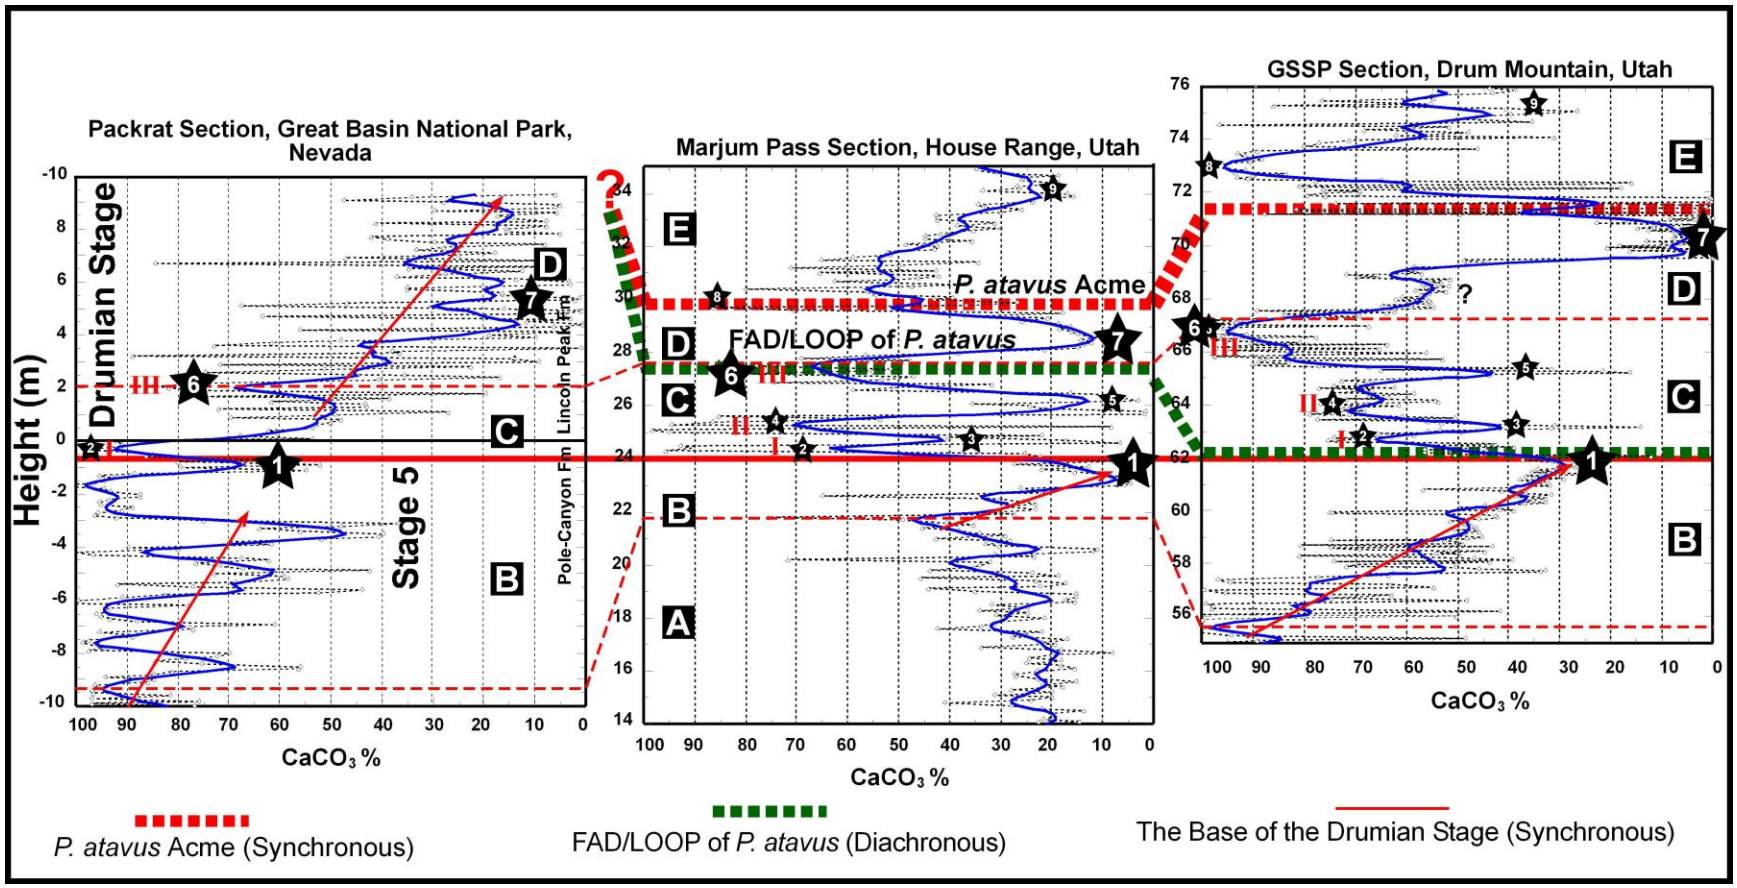

Figure 2.3 Three $CaCO_3$% curves showing high-resolution correlation among the three studied sections (modified from Chapter I). Similar to figure 2.2, the nine correlation star points (CPs: CP1-CP9), the red arrows, and the five intervals (A to E) are placed on the $CaCO_3$ curves for correlation purposes. The base of the Drumian Stage was traced from the GSSP (Babcock et al., 2007) to the Packrat through the Marjum pass at the base of the first storm layer (CP2). The stratigraphic position of the acme and the FAD/LOOP of *P. atavus* are presented as thick red and green dashed lines respectively**.**

2.5. Discussion

2.5.1 The base of the Drumian Stage

The three storm layers (I, II, and III; Figs. 2.2 and 2.6) represent lithostratigraphic markers that facilitate the correlation among the three studied sections and help in tracing the base of the Drumian Stage from the GSSP to the other two sections. The first layer (Figs. 2.6, 2.5, and 2.4) is favored over the other two succeeding storm layers because it has unmistakable χ and $CaCO_3$% signals and can be traced among the HRE sections. It is observed in the HRE trough, northern ramp, and southern ramp sections (Figs. 2.2 to 2.5). However, the second (II) and third (III) storm layers have either vanished or are decreased dramatically in thickness at the southern ramp Packrat section (Figs. 2.2 and 2.3).

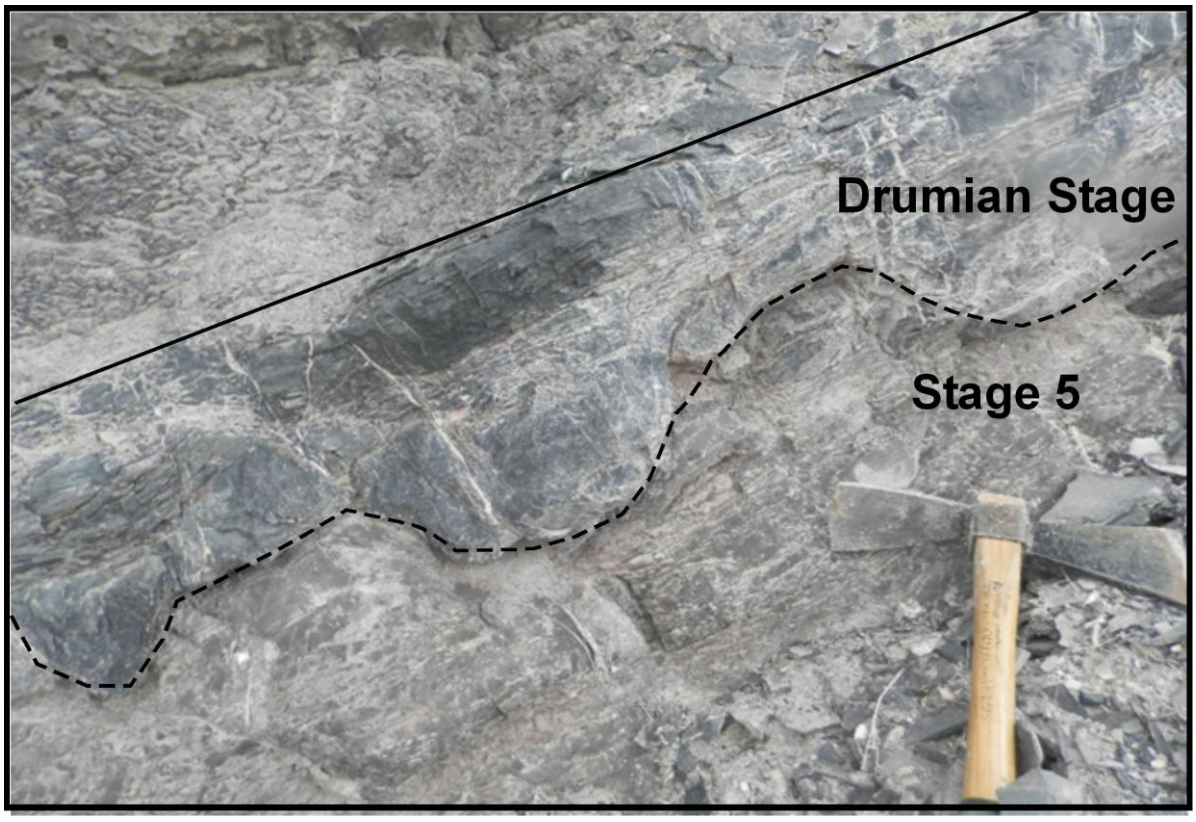

Figure 2.6. Photographs showing the basal boundary of the Drumian Stage at the GSSP section at 62 m above the base of the Wheeler Formation. Ripple marks predominate this erosional surface as it represents the base of the first storm layer, CP2 in figures 2.2 and 2.3. The black dashed line mark this erosional surface.

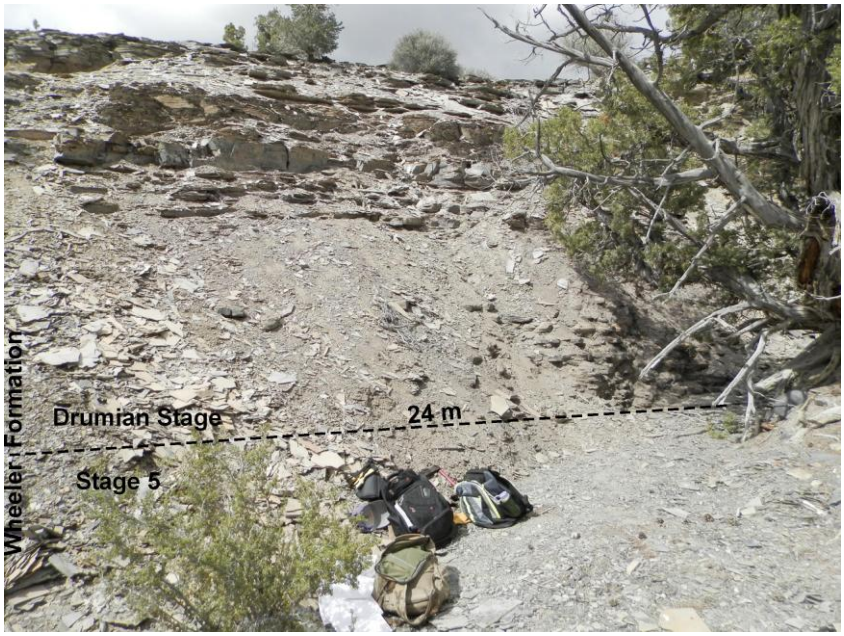

Figure 2.7. Photographs showing the basal boundary of the Drumian Stage at the Marjum Pass section as a black dashed line at 24 m above the base of the Wheeler Formation. The section represent the northern wall of east-west drainage. The back bags are on the drainage bed and the upstream is to the right, east.

Figure 2.8. Photographs showing the basal boundary of the Drumian Stage at the Packrat section as a black dashed line at 0.8 m below the base of the Lincoln Peak Formation. The dark grey layer above the dashed line represents the base of the Drumian stage first storm event (I), at CP2 in figures 2.9 and 2.3 that has high correlation potential among the three sections.

At the GSSP section, the basal boundary of the Drumian Stage was defined at 62 m above the base of Wheeler Formation, at base the first calcisiltite, storm,

layer (Fig. 2.6) (Chapter-I; Babcock et al., 2007; Brett et al., 2009). Consequently, it is traced to 24 m above the base of Wheeler Formation in the Marjum Pass section and ~0.8 m below the Pole-Canyon/Lincoln Peak formations boundary in the Packrat section (Figs. 2.2 and 2.3). These three points mark the base of the first storm layer that is synchronous among the three sections because it is formed within a very short time span. In addition, the storm layer is left undisturbed because bioturbation was insignificant during the middle Cambrian (Gingras and Konhauser, 2015). The synchronicity of the base of the Drumian Stage is supported by high-resolution chemostratigraphic ($\delta^{13}C$ and $\delta^{18}O$) correlation among the studied sections (Chapter-III; Babcock et al., 2007; Howley and Jiang, 2010). The base of the Drumian Stage was reported at 10, 6, 9.5 m below the maximum negative $\delta^{13}C$ excursion at the GSSP, Marjum Pass and Packrat sections respectively where the intervening intervals vary according to SAR (Chapter-III; Babcock et al., 2007; Howley and Jiang, 2010). This negative $\delta^{13}C$ excursion is known as the DrumIan Carbon isotope Excursion or DICE.

2.5.2 The FAD/LOOP of *Ptychagnostus atavus*

The FAD/LOOP of *P. atavus* is diachronous because it is observed at different stratigraphic positions within the three studied sections. At the GSSP section, the stratigraphic position of the FAD of *P. atavus* defines the base of the Drumian Stage at 62 m above the base of the Wheeler Formation, at the base of Storm Layer I (Babcock et al., 2007). At the Marjum Pass section, Robison (1982) reported the LOOP of *P. atavus* at 27 m above the base of the Wheeler Formation. This level is 3 m above the base of the Drumian Stage and lies within Storm Layer III, the third carbonate-dominated storm layer (Figs. 2.2 and 2.3). At the Packrat section, intensive search yielded no *P. atavus* specimens. This makes the work done by

Robison (1982) very important in estimating the position of the LOOP of *P. atavus* in the Packrat section. He reported *P. atavus* at 30 m above the base of Lincoln-Peak Formation. This level is 30.8 m above the base of the Drumian Stage and lies far above the collected section. Consequently, the FAD/LOOP of *P. atavus* is diachronous and lies at 0 m, 3 m and 30.8 m above the base of the Drumian Stage at the GSSP, Marjum Pass, and the Packrats sections, respectively (thick green dashed line; Figs. 2.2 and 2.3). Although the intervening interval increases basinward, it is very thick at the Packrat section and would require an intensive *P. atavus* search below the current reported LOOP and above the collected section to identify a LOOP that is expected to be closer to the actual FAD of *P. atavus* defined at the GSSP.

However, the acme of *P. atavus* is observed to be synchronous between the GSSP and the Marjum Pass sections. This acme is not tested in the Packrat section because the stratigraphic position of *P. atavus* lies above the collected section here. In this study, the search for *P. atavus* was conducted at the Marjum Pass section. Multiple specimens have been recovered from the base of the carbonate-dominated layer, CP8, at ~30 m above the base of the Wheeler Formation (Figs. 2.2 and 2.3). This layer was deposited during a time when sea level was falling and the carbonate factory was prograding, and is located 6 m above the base of the Drumian Stage FAD. It also overlies a detrital-dominated layer, CP7, which was deposited during a maximum sea level rise (Figs. 2.2 and 2.3). Noteworthy is the fact that the multiple recovered specimens from CP8, and CP7 have high correlation potential with the GSSP section (Figs. 2.2 and 2.3). At the GSSP section, a thin limestone coquina with *P. atavus* allochems was recorded at 71 m above the base of the Wheeler Formation (Robison, 1982; Babcock et al., 2007). This level represents the *P. atavus*

acme (Babcock et al., 2007) and lies at the base of carbonate-dominated layer, CP8, which overlies the detrital-dominated layer, CP7 (Figs. 2.2 and 2.3). By extending these markers into the Packrat section, *P. atavus* specimens are expected to be recovered from a carbonate-dominated layer located not too far from the top of the collected section. If proven, the Packrat section would be a good candidate for selection as an alternative Drumian GSSP.

In the GSSP and the Marjum Pass sections, the acme of *P. atavus* is synchronous, and is observed to lie at the base of CP8. This layer, along with underlying layer CP7, was deposited during normal sedimentation, as opposed to storm processes. However the FAD/LOOP of *P. atavus* is diachronous and recorded within carbonate-dominated layers that were deposited during storm events. Even though each storm layer is considered as a chronostratigraphic marker that is synchronous among the HRE sections, it represents reworked sediments and includes reworked *P. atavus* specimens. It is likely that *P. atavus* was living close to the shelf edge of the western Laurentian passive margin. Because the HRE edge, slope, and basinal areas represent an inward extension of their counterparts into the western Laurentian passive margin (Rees, 1986), they are influenced by the same physical processes working on the extensive carbonate platform. During storm events, *P. atavus* was washed off the shelf edge and deposited in slope and basinal areas within reworked sediments. This accounts for the existence of *P. atavus* within the first and third storm event in the GSSP and Marjum Pass sections, respectively. Because the storm sediments are sourced from the northern carbonate platform, the LOOP of *P. atavus* is not observed within the first storm layer in the Packrat section where its carbonates are sourced from the southern carbonate platform.

The HRE paleogeographic setting, ocean circulation pattern, the location of each section, the intensity of the turbidity current, and the slope angle of the seafloor dictate the downslope reach of the carbonate sediments and the stratigraphic position of the FAD/LOOP of *P. atavus* in each section. The paleogeographic setting of the HRE expedites the delivery of *P. atavus* into the HRE during these storm events because it extends more than 400 km into the western Laurentian carbonate platform perpendicular to the trade wind direction (Rees, 1986; Elrick and Snider, 2002). The paleo trade winds likely control the wind pattern, and hence, the shelf currents in the study area (Elrick and Snider, 2002). Rees (1986) mentioned that the existence of pelagic Agnostoid trilobites within anoxic deep-water environments indicates that the HRE water was open to marine currents. Therefore, *P. atavus* is carried by shelf currents or turbidity currents along with carbonate sediments into the HRE. During the storm events, the intensity of the accompanied turbidity currents dictates the downslope grain-size distribution and hence the down reach of *P. atavus*. Proximal sections that are close to the northern HRE edge are expected to have their FAD/LOOP at lower stratigraphic position than distal sections.

2.5.3 A Drumian GSSP alternative

Unfortunately, the FAD at the GSSP was defined at the base of the first storm layer that is composed of reworked sediments and reworked *P. atavus* species (Fig. 2.6). In addition, the stratigraphic position (LOOP) of *P. atavus* is getting higher basinward as the depth and width increase toward the HRE mouth. In western Laurentia, the lowest stratigraphic occurrence of *P. atavus* is expected to be within unnamed Stage Five in the northern HRE edge sections; carbonate-dominated sections. The base of the Drumian Stage was constrained by χ, $CaCO_3$%, and the DICE within the HRE. (See chapter III for more details about DICE as a tool used to

constrain the base of the Drumian Stage). To this end, speculation arises about the validity of the FAD/LOOP of *P. atavus* as a biostratigraphic marker being used to constrain the base of the Drumian Stage when high-resolution correlation is required. Is *P. atavus* a reliable index in defining the Drumian GSSP? This speculation is extended to question the validity of Stratotype Ridge to host the Drumian GSSP section. Is it possible to define the GSSP for the base of the Drumian Stage based on a reworked species at the base of reworked sediments that has an erosional base? If not, do we need to redefine the Drumian GSSP? If yes, do we have an alternative that shows continuous sedimentation and has neither reworked sediments nor reworked *P. atavus* nor erosional base at its GSSP level?

It is the opinion of the authors of this paper that the Drumian GSSP should be redefined to a section that is not frequently interrupted by storm layers and has continuous sedimentation with a decent SAR that assures events separation. However, the new GSSP should be defined using the FAD of *P. atavus,* because it has a narrow stratigraphic range and worldwide geographic distribution (Robison, 1982; Rowell et al., 1982; Robison, 1994; Peng and Robison, 2000; Peng et al., 2004; Babcock et al., 2007). In addition to the FAD of *P. atavus,* other data sets should be developed for the GSSP, such as magnetic polarity, χ, carbonate content, definition of the stable isotope DICE anomaly, other stable isotopic data, elemental geochemistry, and other data where appropriate.

If one were choosing such a succession from the sections studied here, the Packrat section is favored over the Marjum Pass section as a candidate for this GSSP, because, 1) it is least affected by storm events and storm deposits. Storm layers observed in other sections here, have either disappeared in the Packrat section or are reduced dramatically in thickness above the Pole-Canyon/Lincoln

Peak formation boundary. 2) The Packrat section exhibits higher SARs that insure expanded section and thus better event separation (e.g., intervals B and D, Figs. 2.2 and 2.3). Interval D exhibits well-defined short-term cycles during sealevel rise (Fig. 2.3), while these cycles merge in the Marjum Pass section. 3) The Packrat section records sea level fluctuations more effectively than does the Marjum Pass or current GSSP section. The steady χ increase above the base of the Drumian Stage reflects a steady sea level rise that reaches a maximum at the top of the interval D (Figs. 2.2 and 2.3). Even though the Packrat locality exhibits syndepositional folding and sliding surfaces, the intervals that were collected are not significantly affected by this deformation.

2.5.4 Global occurrence of *P. atavus*

The facies changes that coincide with the FAD/LOOP of *P. atavus* within HRE slope and basinal sections is supported globally by multiple studies (Peng and Robison, 2000; Peng et al., 2004; Zhu et al., 2004). Here, the FAD/LOOP of *P. atavus* is observed within carbonate-dominated sediment layers that either formed during storm events and intercalate with detrital-dominated layers, or formed during sea level falls and basinward progradation of shelf carbonate sediments over slope and basinal detrital-dominated intervals. Even though the location of each section studied here dictates the carbonate/detrital ratios within the carbonate- and/or the detrital-dominated intervals, χ and $CaCO_3$% analysis of high-resolution samples account for these lithological variations (Figs. 2.2 and 2.3). In south China, the facies change in the Wangcun section at the LOOP of *P. atavus,* from black shale with increasing amounts of dark gray, to thin-bedded limestone interbeds, to dark gray, thin-bedded limestone lacking black shale interbeds within the lower member of the overlying Huaqiao Formation (Peng and Robison, 2000; Peng et al., 2004; Zhu

et al., 2004) (Fig. 2.10). Consequently, factors that account for the LOOP of *P. atavus* in slope and basinal sections of western Laurentia, likely also hold true for the equivalent aged slope sections of the south China region. For global correlation to be successful, high-resolution studies between the slope and basinal sections of western Laurentia and southern China, using abiotic techniques such as χ, $CaCO_3$%, and stable isotopic analyses, are needed.

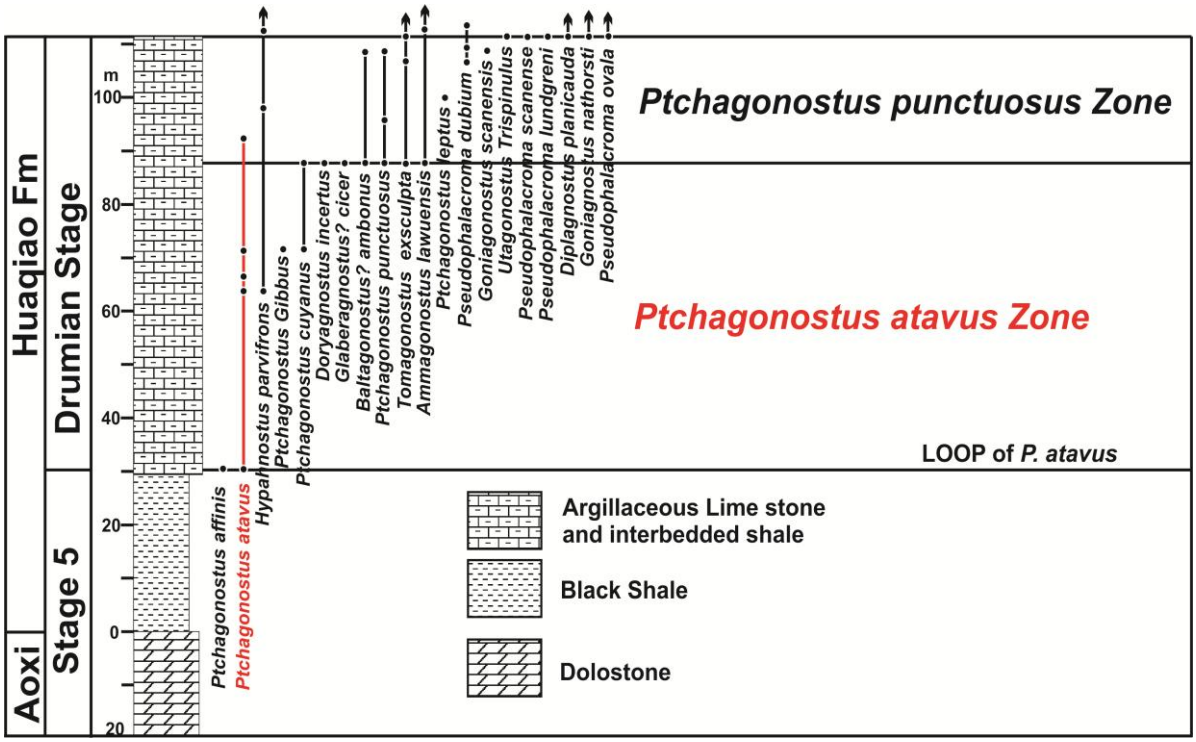

Figure 2.10. A biostratigraphic chart representing bizones and the associated facies at the base of the Middle-Cambrian Drumian Stage in the Wangcun section, western Hunan Province, China (modified from Peng and Robison, 2000; Peng et al., 2009). The LOOP of *P. atavus* resides at the base of the carbonate-rich interval that overlie a detrital-dominated layer close to the Aoxi/Huaqiao formation boundary. This signal is similar to its counterpart at the HRE sections.

2.6. Conclusions

Field observations along with closely-spaced sampling provide high resolution correlation among three Middle Cambrian succession deposited in the House Range Embayment (HRE), formed along the western margin of Laurentia during the Cambrian. These high-resolution data sets help unravel multiple key geological elements that would be difficult to explain with coarse correlation, widely-spaced

sampling techniques. The base of the Drumian Stage is traced from the Global boundary Stratotype Section and Point (GSSP) into two other HRE sections by using the base of the lowest storm-deposited turbidite layer as the 1st (I) event horizon. This layer is a lithostratigraphic marker unit that helps to constrain not only the basal boundary of the Drumian Stage, defined by the First Appearance Datum (FAD) of the Agnostoid trilobite, *P. atavus* at the GSSP, but also the Lowest Occurrence Observed Point (LOOP) of *P. atavus* and the DrumIan Carbon Isotope Excursion (DICE) within other HRE slope and basinal localities. The first storm layer (I) is found in the GSSP HRE shallow trough section, and can be traced into the Marjum Pass downslope section on the HRE northern ramp, and into the downslope Packrat section on the HRE southern ramp. The thickness of this layer is expected to be minimal far from the GSSP, or even to vanish in the downslope sections of the northern ramp close to the HRE mouth, where the HRE has its greatest depth and width. However, this using magnetic susceptibility (χ), CaCO3%, and $\delta^{13}C$ and $\delta^{18}O$ stable isotope data, Layer I was unambiguously identified in the Marjum Pass and Packrat successions.

In the GSSP and the Marjum Pass sections, the acme of *P. atavus* is synchronous and observed at the base of a carbonate-dominated layer, CP8. This layer, along with the underlying CP7 layer, were deposited during normal sedimentation process. However, the FAD/LOOP of *P. atavus* is found to be diachronous in the HRE and recorded within carbonate-dominated storm layers. Unfortunately, the GSSP was defined at the base of the first storm layer that has an erosional base and is composed of reworked sediments and reworked *P. atavus* specimens. Consequently, it is argued here that the base of the Drumian Stage should be redefined. The Packrat section in the Snake Range within Great Basin

National Park, eastern-most Nevada, USA, represents a good candidate for a new GSSP location, because it is least affected by the storm deposits in the HRE, has high sediment accumulation rates that assure better event separation, and therefore records sea level fluctuations more effectively.

Globally, the Lowest Occurrence Observed Point (LOOP) of *P. atavus* occurs within carbonate-dominated facies in the slope and basinal sections of western Laurentia and southern China. These facies were formed either during storm events and intercalate with detrital-dominated layers, or during sea level falls and basinward progradation of shelf carbonate-dominated sediments over slope and basinal detrital-dominated intervals.

CHAPTER III: HIGH-RESOLUTION STABLE ISOTOPE ($\delta^{13}C$ AND $\delta^{18}O$) CORRELATION AMONG THE HOUSE RANGE EMBAYMENT AND PLATFORM SECTIONS ACROSS THE BASE OF THE CAMBRIAN DRUMIAN STAGE, WESTERN LAURENTIA

Globally, the stratigraphic position of the Middle Cambrian DrumIan Carbon isotope Excursion (DICE) is observed to fall below, above, and to straddle the First Appearance Datum (FAD) of *Ptychagnostus atavus*, the Agnostoid trilobite that defines the base of the Drumian Stage (Babcock et al., 2004; Zhu et al., 2004; Zhu et al., 2006; Babcock et al., 2007; Howley and Jiang, 2010). In addition, the interval over which the DICE occurs is variable among marine slope and platform sections. Coarsely sampled data sets fail to provide an explanation for these inconsistencies. This study provides high-resolution correlation among three slope and basinal sections from the House Range Embayment (HRE) along the western Laurentian margin, where hundreds of samples have been analyzed to test the DICE synchronicity regionally within the HRE. Published chemostratigraphic data (Howley, 2010; Howley and Jiang, 2010) are used to extend this test into carbonate platform sections located to the south of the HRE.

It is concluded that the DICE is a chronostratigraphic marker that constrains the base of the Drumian Stage in the embayment and platform sections, except for where stable isotope values are suppressed by incoming heavy-isotopic platform carbonates. Here it is argued that the DICE maximum negative $\delta^{13}C$ excursion is locally synchronous and should be used for correlation among multiple coeval western Laurentia successions, because the DICE event marks the maximum sea level rise that follows the defined base of the Drumian Stage. However, the onset and the end of the DICE event are diachronous among the studied sections, and should not be used as stratigraphic datum when high-resolution correlation is desired.

The DICE event is interpreted to result from respiration and remineralization of organic matter that is included in the Middle Cambrian Oxygen Minimum Zone (OMZ). It is inferred that the OMZ was well-developed either, 1) only across the base of the Drumian Stage and imprinted the HRE and southern platform sections during this particular sea level rise rather than earlier or later sea level rises, or 2) during the entire Middle-Cambrian and sea level rose to an unprecedented level across the base of the Drumian Stage, elevating the OMZ to high levels, and allowing organic matter respiration through mixing with oxygen-rich surface water. The DICE event is observed on the southern HRE platform because HRE poorly-oxygenated, organic-rich, deep water was brought to the carbonate platform by trade wind driven surface currents.

The base of the Drumian Stage is argued to lie below the DICE on the southern platform at one of the erosional surfaces that have been observed by Howley and Jiang (2010), close to the maximum $\delta^{13}C$ excursion. High-resolution χ, Total Organic Carbon (TOC), and carbonate percent analysis are needed for the platform sections to examine which of these surfaces represent the Drumian Stage basal boundary.

3.1. Introduction

The DICE and the First Appearance Datum (FAD) of *P. atavus*, that have been observed in the Global boundary Stratotype Section and Point (GSSP) of the Cambrian Drumian Stage in the Drum Mountain of western Utah, are considered to be a worldwide chemostratigraphic and biostratigraphic markers that helps to constrain the base of the Drumian Stage (Peng and Robison, 2000; Babcock et al., 2004; Peng et al., 2004; 2007; Howley and Jiang, 2010). However, the precise stratigraphic position for LOOPs of *P. atavus* and DICE are tentative and uncertain.

The LOOP of *P. atavus* is reported to be diachronous and is recorded within carbonate-dominated storm deposits regionally within the HRE (Chapter II). Globally, the DICE is actually either below, above, or it straddles the LOOP of *P. atavus,* even in sections that exhibit similar depositional environments. For example, in south China a negative carbon isotopic excursion is observed below the LOOP of *P. atavus* in the Huaqiao Formation within a section at Wangcun (Zhu et al., 2004). In the USA, the DICE is located 72 m above the base of the Wheeler Formation within the GSSP section, which is 10 m above the FAD of *P. atavus* (Babcock et al., 2005; Babcock et al., 2007). In addition, Zhu et al. (2006) reported that the LOOP of *P. atavus* is associated with the end of the DICE, where the DICE event is shown to straddle the base of the Drumian Stage in the Cambrian $\delta^{13}C$ composite curve. In Southern Sweden, the DICE is maximum in a thin limestone bed above the base of *P. atavus;* this based on organic $\delta^{13}C$ values (Ahlberg et al., 2009).

Both the GSSP and Wangcun sections have similar depositional environments because they are slope sections of the western Laurentian carbonate platform (Rees, 1986) and the Yangtze carbonate platform in China (Zhang et al., 2001) respectively. In addition, carbonates shed off the two platforms, and terrigenous materials are fed by ocean currents to both localities (Chapter-I; Zhang et al., 2001). Still, the stratigraphic positions of the negative $\delta^{13}C$ excursions and *P. atavus* are reversed. Without providing a reasonable explanation for the stratigraphic uncertainty of these two worldwide important markers within slope and basinal sections, their correlation and extrapolation into shallow shelf areas will be difficult.

In western Laurentian slope and basinal sections, the DICE chemostratigraphic interpretations are improving as high-resolution data sets are obtained. In 2003, the DICE was missed during sequence stratigraphic and

geochemical studies on the Wheeler Formation at the GSSP and at Marjum Pass (Langenburg). In Babcock and others (2004; 2007), the DICE was poorly-represented by only one data point in the GSSP section. Howley and Jiang (2010) reported the DICE onset at 7 m above the FAD of *P. atavus* at the GSSP and 3 m above the LOOP of *P. atavus* at the Marjum Pass section, based on 2 and 4 data points, respectively. However, inconsistency still exists among these studies due to inadequate chemostratigraphic resolution.

The present study provides high-resolution correlation among three HRE slope and basinal sections where hundreds of samples have been analyzed to test DICE synchronicity regionally within the HRE across the base of the Drumian Stage. These studied sections are, 1) the GSSP section, Drum Mountain, Utah, 2) the Marjum Pass section, House range, Utah, and 3) the Packrat section, Great Basin National Park, Snake Range, Nevada. In addition, this work is extended to three southern carbonate platform sections, Wah Wah, Panaca Hills and Desert Range, using the chemostratigraphic work of Howley and Jiang (2010) and Howley (2010).

3.2. Geological background

Laurentia is the name for the North American continent that formed during the late Neoproterozoic by the breakup of the Rodina Supercontinent (Rees, 1986). An extensive carbonate belt covered the passive margin of western Laurentia during the Middle-Cambrian. This carbonate belt is known as the Great American Carbonate Bank (GACB), and was built up mainly from algal and/or microbial carbonate-rich sediment (Palmer, 1971; Brady and Koepnick, 1979; Aitken, 1997). The GACB was bounded by Panthalassic deep-water sediments to the west and by shoreline sediments to the east (Rees, 1986). A normal fault cut through this extensive carbonate belt and propagated eastward for ~400 km, creating the HRE (Rees,

1986; Hintze, 1988) (Fig. 3.1). The HRE represents a half-graben structure that is bounded by the normal fault to the south, and composed of trough, northern and southern ramps. The trough is the deepest part of the embayment that is parallel to the fault propagation direction; the northern ramp is a drowning platform that formed as a southward sloping ramp; and the southern ramp is a high-slope-angle ramp that has syndepositional structures, including syndepositional folding, sliding and density flow (Chapter-I; Rees, 1986). The HRE depth and width, as well as fault displacement, increase westward and reach to their maximum at the HRE mouth, where the HRE meets Panthalassic Ocean deep-water at the western edge of the Laurentian passive margin (Rees, 1986).

The Middle-Cambrian Wheeler Formation is known to have multiple intervals of high fossil preservation potential (Gaines and Droser, 2005; Gaines et al., 2005; Halgedahl et al., 2009). This exceptional preservation is the result of low bioturbated, clay-rich, and low permeability facies that were deposited under poorly oxygenated, organic-rich, bottom water conditions (Gaines et al., 2005). In the GSSP section, a detrital-rich and carbonate-poor interval has been observed in the lower Wheeler Formation, at ~71 m above its base (Chapter-II). A similar interval has been observed in the Drum Mountains in the upper Wheeler Formation, at ~230 m above its base (Halgedahl et al., 2009). This interval is called a “hot zone” and has similar magnetic susceptibility (χ) and $CaCO_3$% signals. It is likely that these two intervals were formed under similar depositional environments even though the exceptional soft-bodied preservations that have been documented in the upper Wheeler hot zone, is not observed in the lower Wheeler interval. Instead, a thin limestone coquina that is composed almost entirely of *P. atavus* allochems has been observed in the lower interval (Babcock et al., 2007). Although the Middle-Cambrian HRE sequence

was subjected to four compressional events during the Paleozoic and Mesozoic, and extensional periods during the Cenozoic that displaced and distorted its original configuration, the studied sections lie in areas that have little deformation (Dickinson, 1981; Robison, 1982; Speed, 1982; Rees, 1984; Rees, 1986).

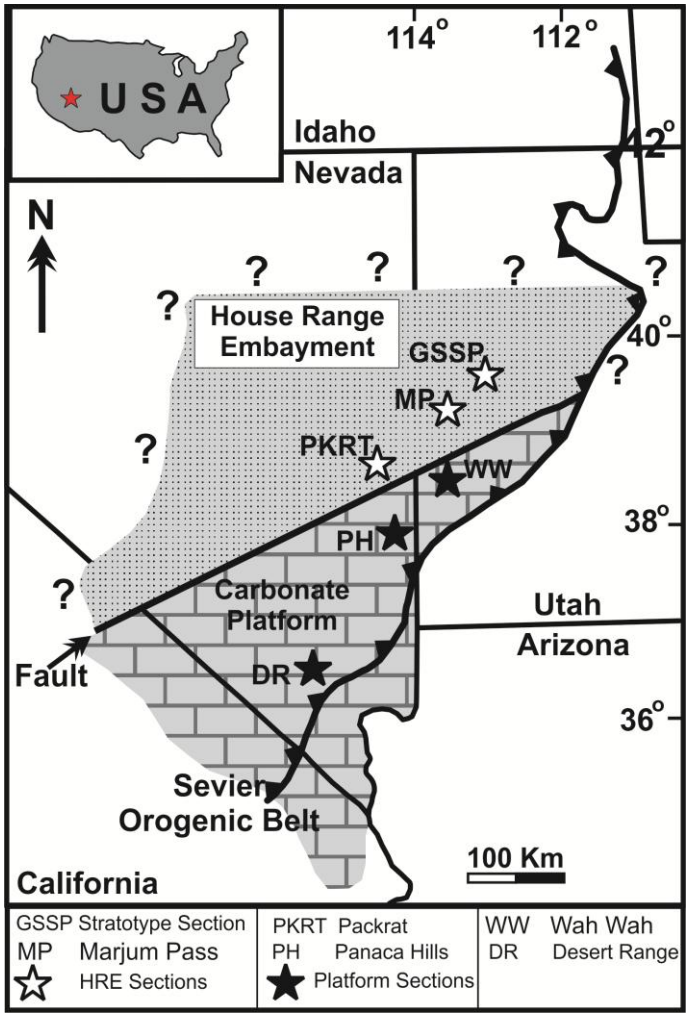

Figure 3.1. Non-palinspastic reconstruction map showing the location of the studied House Range Embayment (HRE) sections (GSSP, Marjum Pass and Packrat) as open stars and Platform sections (Wah Wah, Panaca Hills and Desert range) as black fill stars (modified from Palmer, 1971; Elrick and Snider, 2002; Howley et al., 2006). A NE–SW normal fault separates the Laurentian carbonate shelf facies of the southern platform from the slope, mixed siliciclastic-carbonate facies of the HRE.

3.3. Methods

In HRE slope and basinal sections, 372 samples were selected for isotopic analysis; this includes 103 samples from the GSSP, 97 samples from Marjum Pass, and 172 samples from the Packrat sections. The sampling interval ranges between

0.1 m and 0.5 m. Stable isotope analysis of carbonates ($\delta^{13}C$ and $\delta^{18}O$) were performed at Oxy-Anion Stable Isotope Consortium (OASIC) laboratory at LSU. Samples were calibrated using two working standards for every 10 samples. The $\delta^{13}C$ and $\delta^{18}O$ of the working standards are 2.57 ‰ and -4.31‰, respectively, to the Vienna Pee Dee Belemnite "VPDB" standard. 200±20 µg of each sample was placed into a vial and flushed with 99.999% pure Helium for 2 minutes at a flow rate of 80 ml per minute. The sample was allowed to react with high concentrated phosphoric acid for 3 hours. The resulting CO_2 output was processed and run through a Thermo Finnigan MAT 253 mass spectrometer for analysis. The reader is referred to Howley and Jiang (2010) for the materials and methods used for the isotopic analyses for the southern carbonate platform sections from western Laurentia.

3.4. DICE results and Interpretation for HRE sections

$\delta^{13}C$ and $\delta^{18}O$ data are presented versus the height in each section in figures 3.2 to 3.6. These curves cover the interval from the Middle-Cambrian uppermost part of unnamed Stage Five into the lowermost part of the Drumian Stage. In this study, the base of the Drumian Stage was traced from the GSSP section through the Marjum Pass and into the Packrat sections, using data from the base of the first storm layer (Layer I) identified by (Chapter-I and II). Regression analysis between $\delta^{13}C$ and $\delta^{18}O$ shows very low correlation at each of the three sections, indicating only minimal alteration effects in these sections (Figs. 3.2-c to 3.4-c). However, individual data points that do exhibit high correlation among these sections have been eliminated to avoid alteration effects biasing interpretation in the stable isotope data. The raw data are presented as black dashed lines with all data points included while the blue solid lines represent their splines (Figs. 3.2 to 3.6). The red arrows show trends of change in $\delta^{13}C$ and $\delta^{18}O$ curves.

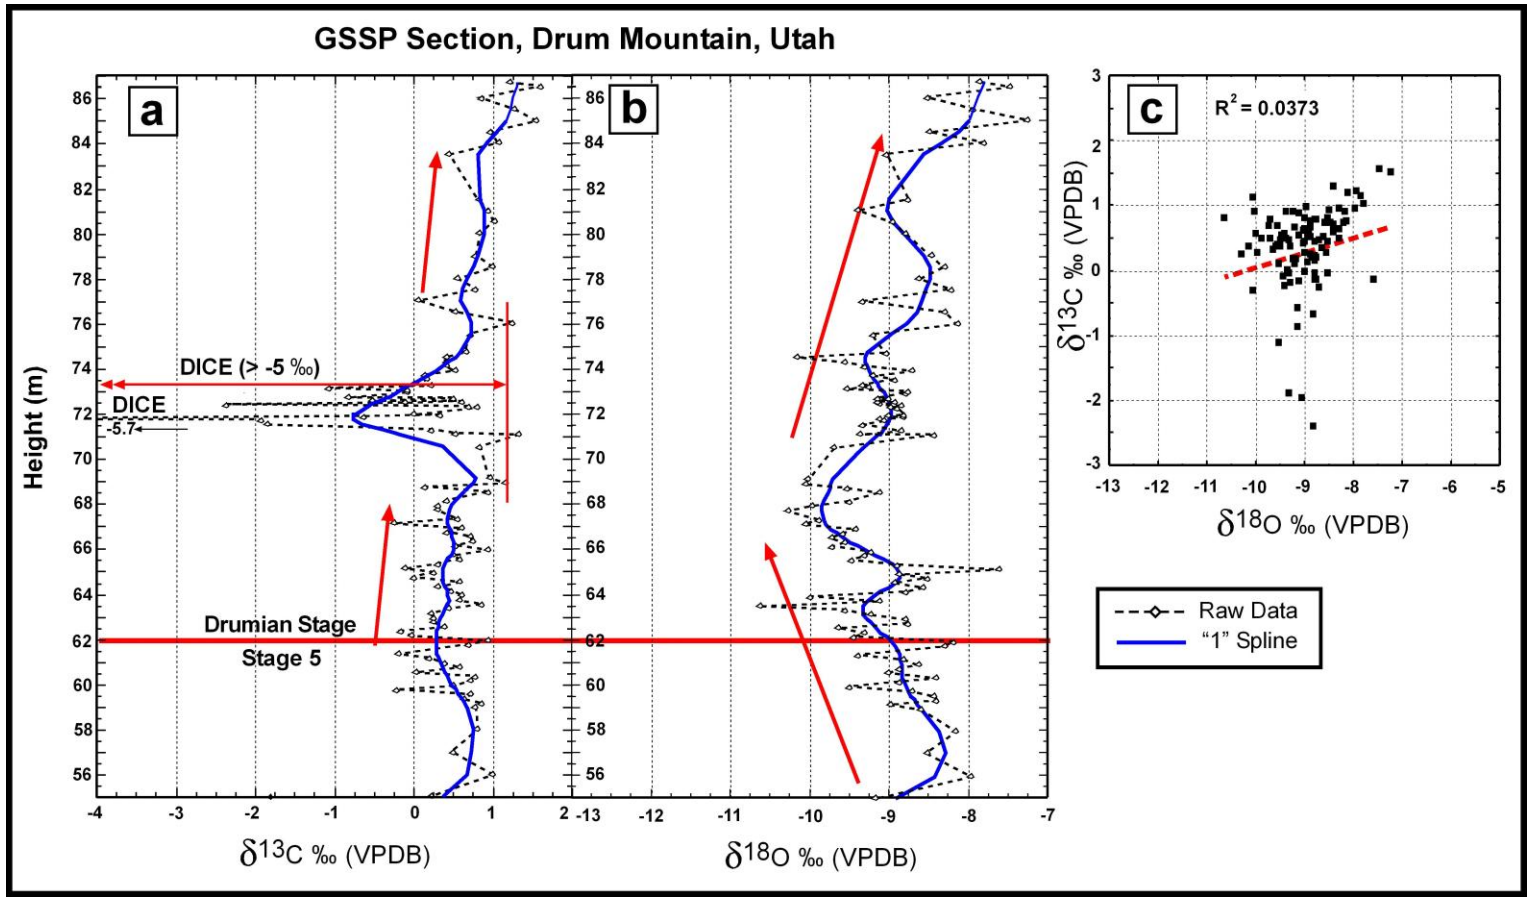

Figure 3.2. Three curves showing $\delta^{13}C$, $\delta^{18}O$ and their regression analysis obtained from the GSSP section showing the raw data as a black dashed line with data points included, and splined data as a solid blue line. (a) is the $\delta^{13}C$ curve. The maximum DICE excursion is shown by the double-headed arrow. (b) is the $\delta^{18}O$ curve. (c) represents the regression analysis between $\delta^{13}C$ and $\delta^{18}O$ with regression line and its coefficient (R^2) included. The base of the Drumian Stage is defined at 62 m in the section (Chapter-I; Babcock et al., 2007). The height of the GSSP is measured from the base of the Wheeler Formation.

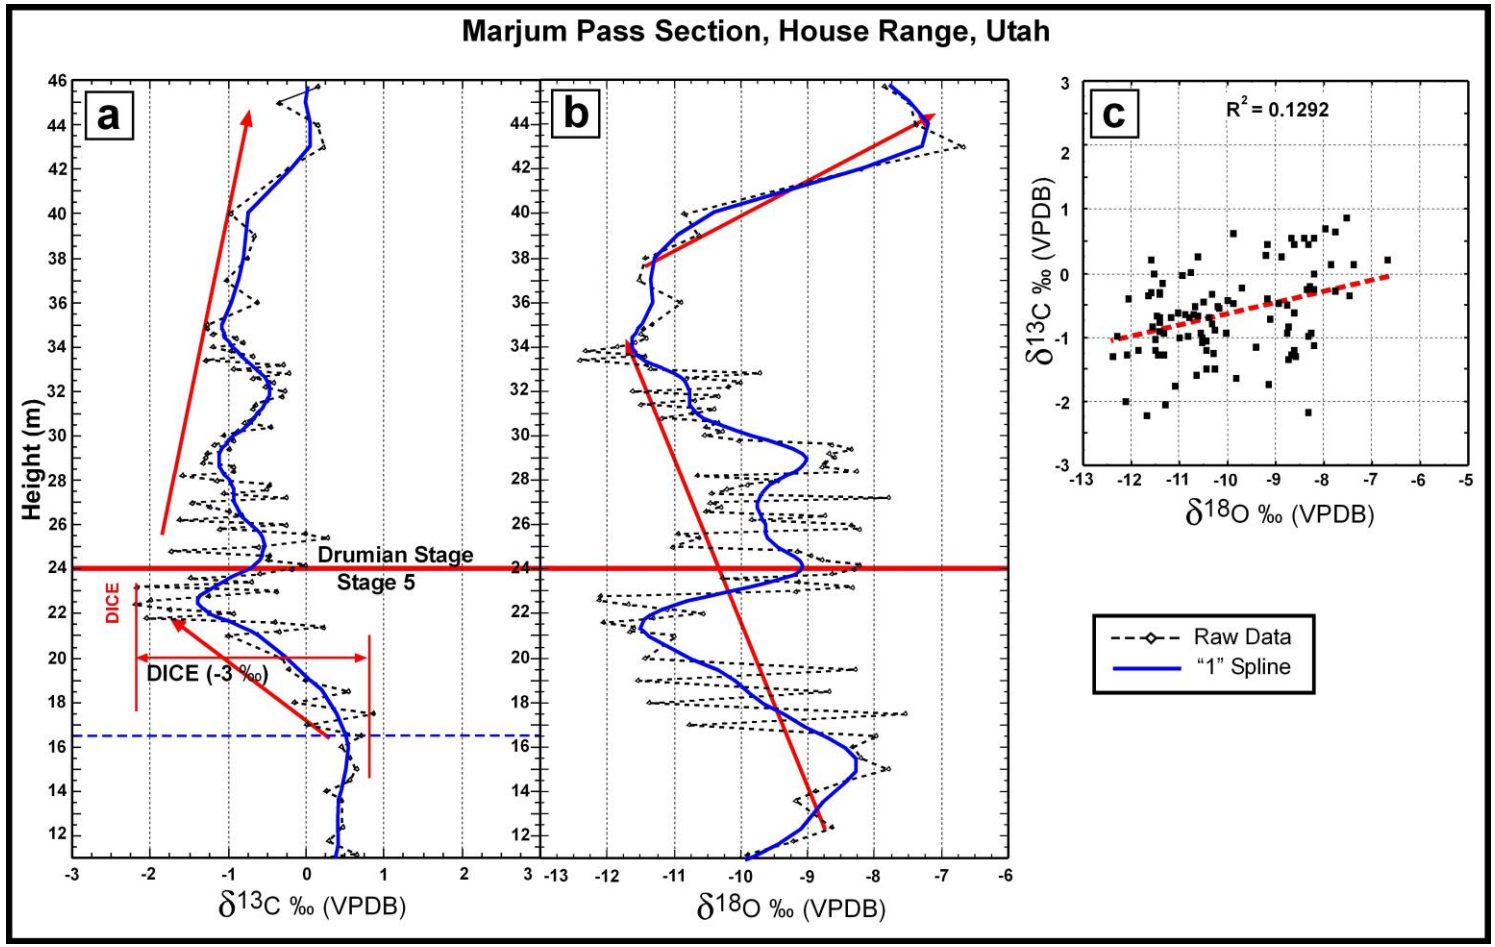

Figure 3.3. Three curves showing the isotopic results obtained from the Marjum Pass section. The features on the three curves, (a to c), are illustrated in the caption of figure 3.2. The base of Drumian Stage here is defined at 24 m (Chapter-II). The height of the Marjum Pass section is measured from the base of the Wheeler Formation.

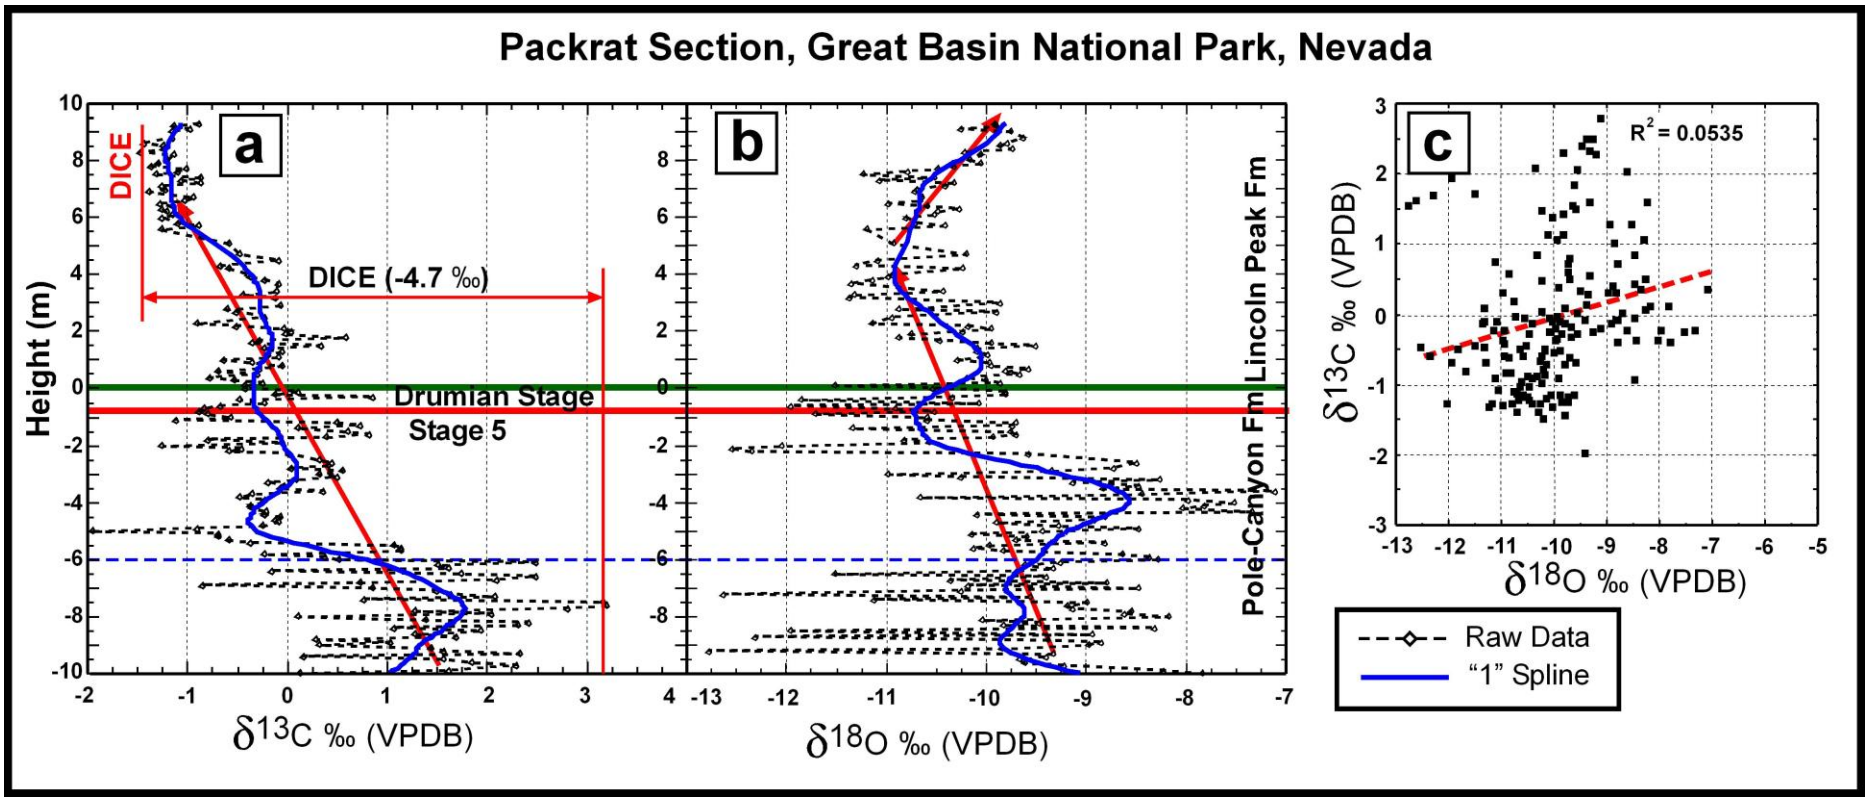

Figure 3.4. Three curves showing the isotopic results obtained from the Packrat section. The features on the three curves (a to c) are illustrated in the caption of figure 3.2. The base of Drumian Stage is defined at ~0.8 m (Chapter II) below the base of the Lincoln Peak Formation.

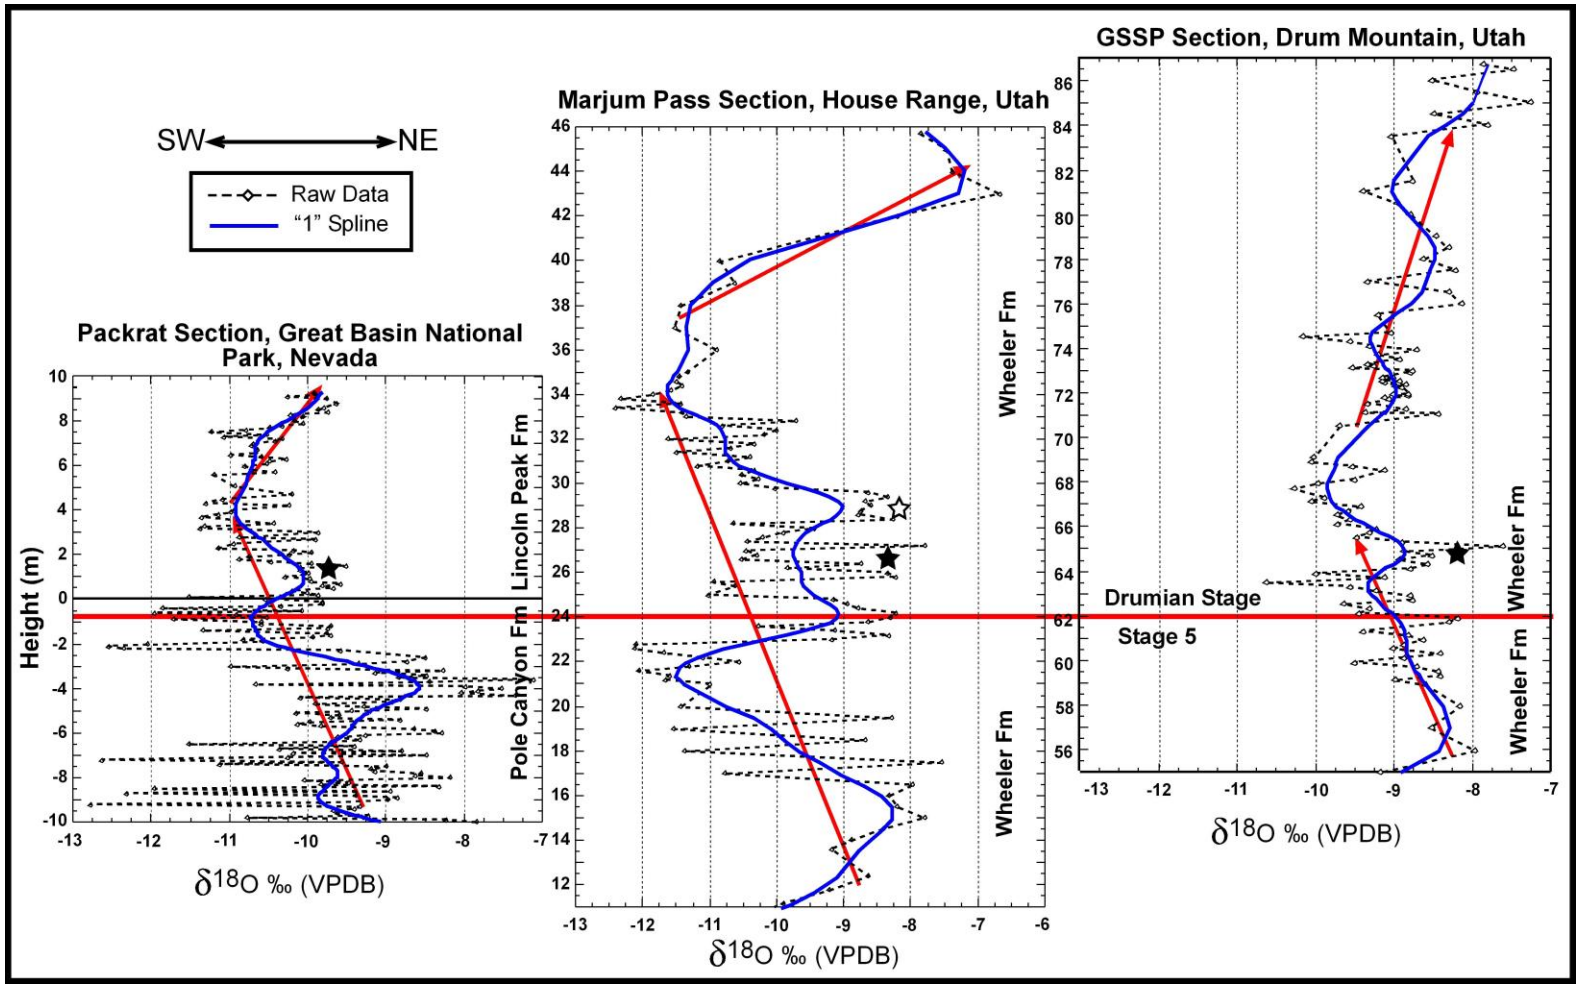

Figure 3.5. Three $\delta^{18}O$ curves showing high-resolution correlation among the three HRE sections; GSSP, Marjum Pass and Packrat. The black filled stars represent heavy isotopic intervals (peaks) above the base of the Drumian Stage. These have high correlation potential among the three sections and coincide with storm deposits. The open star at the Marjum pass section represents a heavy isotopic peak that coincides with a sea level fall and carbonate progradation to the embayment. The red arrows represent long-term changes in the $\delta^{18}O$ curves.

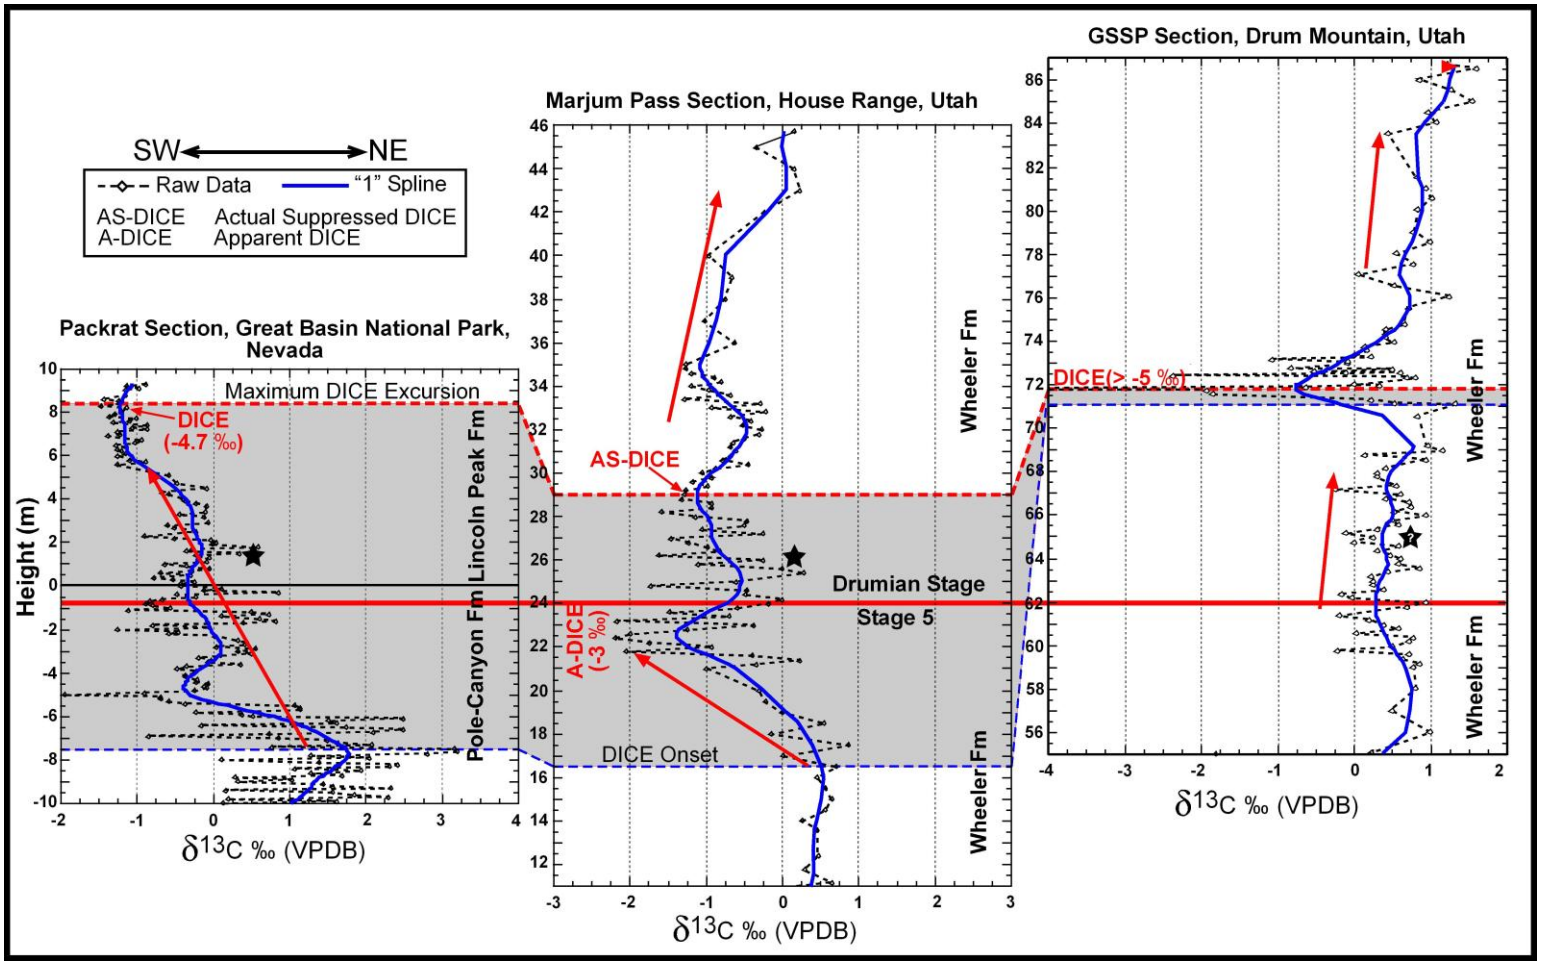

Figure 3.6. Three $\delta^{13}C$ curves showing high-resolution correlation among the HRE sections; GSSP, Marjum Pass and Packrat. Black filled stars represent heavy isotopic intervals (peaks) above the base of the Drumian Stage at the Packrat and Marjum Pass sections. The DICE maximum excursion and its onset are represented by the dashed red and blue lines respectively. The A-DICE is the apparent DICE and the AS-DICE represent the Actual Suppressed DICE. This carbonate layer suppresses the DICE signal because it has heavy isotopic values than its containing facies. The red arrows represent long-term changes in the $\delta^{13}C$ curves.

Most of $\delta^{18}O$ values exhibit ~4 ‰ ranges in all three sections except for the GSSP section where it shows ~2 ‰ range. $\delta^{18}O$ represent negative long-term excursion that is highlighted by the red arrows and correlates among the three sections (Fig. 3.5). However, the Packrat section does not show the following $\delta^{18}O$ increase because it is stratigraphically shorter than the other two sections. Multiple peaks are superimposed on the long-term decreasing trends, red arrows, showing a distinctive peak (black star) above the base of the Drumian Stage in all three sections (Fig. 3.5). This Peak is more prominent in the Marjum Pass section, showing higher amplitude and covering longer interval than its equivalents in GSSP and the Packrat sections. Another unique peak is observed at 4 m below the Pole-Canyon/Lincoln-Peak formations boundary in the Packrat section (Figs. 3.4-b and 3.5). This peak marks a debris flow that originated from up-ramp, shallower areas on the southern HRE ramp (Chapter-I), and isn't found in the other two sections.

$\delta^{13}C$ values have slightly more variability among the three sections than do $\delta^{18}O$ values (Fig. 3.6). In the GSSP section, $\delta^{13}C$ values range between 0‰ and 1‰ except at ~72 m above the base of the Wheeler Formation, where values fall to more than -5‰. $\delta^{13}C$ ranges between -2.2‰ and 0.8‰ in the Marjum Pass section, and between -1.5‰ and 3.2‰ in the Packrat section. $\delta^{13}C$ long-term changes also vary form one section to the other (Fig. 3.6). The GSSP section shows overall minor increases that are interrupted by a sharp, -5‰ $\delta^{13}C$ excursion at 72 m. In the Marjum Pass section, $\delta^{13}C$ decreases from ~0.8‰ at 16.5 m to reach a minimum (-2.2‰) at ~23 m above the base of Wheeler Formation, 1 m below the base of the Drumian Stage. Values then increase to ~0‰ at the top of the section. The Packrat section has a unique $\delta^{13}C$ signal, where values decrease gradually from ~3.2‰, at 7.5 m

below the Lincoln-Peak/Pole-Canyon formations boundary, to a minimum (-1.5‰) at 8.5 m above the same boundary, an overall shift of nearly -4.7‰ (Fig. 3.6). This signal started below and ended above the base of the Drumian Stage. Above the base of the Drumian Stage, $\delta^{13}C$ values exhibit heavy isotopic peaks (black star) in the Packrat and Marjum Pass sections, but this peak is absent in the GSSP section.

In summary, the position of the maximum negative $\delta^{13}C$ excursion varies in the three sampled sections relative to the base of the Drumian stage. It is located at 10 m and ~9.5 m above the base of the Drumian Stage in the GSSP and the Packrat sections, respectively, and 1 m below the same stage boundary at the Marjum Pass section. Moreover, the interval over which $\delta^{13}C$ decreases to its minimum values decreases along the HRE to the southwest from ~1 m (71 to 72) at the GSSP, to 6.5 m (16.5 to 23) at the Marjum Pass Section, to 16.5 m (-7.5 to 8.5) at the Packrat section (Figs. 3.1 and 3.6). Accordingly, the overall negative excursion is sharp in the GSSP section, moderate in the Marjum Pass section, and gradual in the Packrat section (Fig. 3.6). Furthermore, this interval straddles the base of the Drumian Stage in the Packrat section, is below the boundary in the Marjum Pass section, and above it in the GSSP section.

This negative $\delta^{13}C$ excursion was reported to be synchronous and represent the DICE in the GSSP and Marjum Pass sections (Babcock et al., 2004; 2007; Howley and Jiang, 2010), irrespective of its relation to the base of the Drumian stage or the LOOP of *P. atavus* in the Marjum Pass section. The DICE excursion is argued here to include the negative carbon isotope excursion observed in the Packrat section at ~9.5 m above the base of the Drumian Stage, because the three sections are well correlated based on χ and $CaCO_3$% signals as demonstrated by (Chapter-I). In addition, the Packrat $\delta^{13}C$ negative excursion lies within the expected range.

3.5. Discussion

Isotopic values for slope and basinal sections tend to fluctuate according to the major facies changes during sea level rise across the base of the Drumian Stage. In chapter-I the lithological variations among the three sections reported here have been studied in detail using χ and $CaCO_3$%. This results in tracing a series of layers across the HRE. $\delta^{13}C$ and $\delta^{18}O$ values covary with such lithologic variations and tend toward heavier values when higher $CaCO_3$% layers are encountered. These carbonate-rich layers were deposited either during storm events or during the carbonate platform progradation that follows maximum sea level rise (Chapter-I). In addition, $\delta^{18}O$ response to these carbonate dominated layers is more conspicuous than $\delta^{13}C$. Marjum Pass curve, for example, shows prominent $\delta^{18}O$ flat peak above the base of the Drumian Stage that is >3‰ heavier than its bounding $\delta^{18}O$ values, while $\delta^{13}C$ of the same interval is only ~1‰ heavier than its bounding $\delta^{13}C$ values and superimposed on the long-term $\delta^{13}C$ increase (Fig. 3.3).

Laterally, $\delta^{13}C$, like $\delta^{18}O$, behaves differently for the same layers at different localities. The shallow sections that are very close to the HRE northern edge (GSSP) or deep sections that are very close to the HRE trough (Packrat) have less isotopic variations than the lower-slope section of the northern HRE ramp (Marjum Pass). Above the base of the Drumian Stage, both the GSSP and Packrat sections show lower amplitude $\delta^{18}O$ and $\delta^{13}C$ peaks than their equivalent in Marjum pass section (Figs. 3.5 and 3.6). Another $\delta^{18}O$ peak is observed at 4 m below the Pole Canyon/Lincoln Peak formations boundary in the Packrat section. This peak coincides with the debris flow layer that originated from shallower areas on the southern HRE ramp. This $\delta^{13}C$ peak is less well defined and is only observed in the Packrat section (Chapter-I).

The overall lithological composition varies among the three studied sections. The GSSP is a carbonate-dominated section; Marjum Pass is a detrital-dominated section, and the Packrat section is mixed, being carbonate-dominated during Stage 5 and detrital-dominated during the Drumian Stage (Chapter-I). Higher carbonate percentages shift $\delta^{13}C$ signal to heavier values, delay the DICE onset to higher stratigraphic position, and accelerate the DICE ending to lower stratigraphic position within carbonate-dominated sections more than in detrital-dominated sections. Therefore, the DICE begins stratigraphically earlier in the Marjum Pass section and later in the GSSP and Packrat sections (Fig. 3.6). Likewise, it ends earlier in the GSSP section, and has its highest termination in the Packrat section because the Packrat is more detrital above the base of the Drumian Stage than the other two sections (Chapter-I). In addition, the $\delta^{13}C$ negative excursion tends to be more gradual and cover longer stratigraphic intervals within sections that are not frequently interrupted by deposition of carbonate-dominated layers (i.e., Packrat), versus those dominated by carbonate layers (i.e., GSSP) (Fig. 3.6). The DICE negative excursion is gradual in the Packrat section, moderate in the Marjum Pass section and very rapid in the GSSP section.

Multiple explanations have been provided for the DICE negative $\delta^{13}C$ excursion. Meteoric diagensis due to fresh-water supply, carbon recycling in restricted basins, and/or significant diagenetic modifications below sequence boundaries may account for $\delta^{13}C$ negative excursions (Allan and Matthews, 1982; Holmden et al., 1998; Panchuk et al., 2006; Theiling et al., 2007; Howley and Jiang, 2010). However, based on the results presented here, the most acceptable explanation for the DICE event is respiration and remineralization of organic matter (Patterson and Walter, 1994; Howley and Jiang, 2010) that is stored within the

Oxygen Minimum Zone (OMZ). It is likely that the OMZ was well developed across the base of the Drumian Stage within slope and basinal areas of the passive margin of western Laurentia. Accordingly, the HRE deep-water was poorly oxygenated, and the oxygen level decreased with depth until it reached minimum, dysoxic or possibly even anoxic levels, in the OMZ. Oxidation of organic matter is known to pump lighter carbon (^{12}C) into containing and surrounding water masses (Lloyd, 1964; Patterson and Walter, 1994; Panchuk et al., 2006). This process leads to $\delta^{13}C$ depletion of the dissolved inorganic carbon (DIC) in containing ocean water faster than other processes (Panchuk et al., 2006). In modern semi-restricted marine environments such as Florida Bay and the Bahamian Banks, $\delta^{13}C$ in sediments is observed to be more than 4‰ below the surrounding open-ocean water (Lloyd, 1964; Patterson and Walter, 1994). Ocean water above the HRE appears to have been stratified during deposition of the lower Wheeler Formation (Rees, 1986; Gaines and Droser, 2003; Gaines et al., 2005). However, the Laurentian shallow-water carbonate platform was deposited under well oxygenated conditions, because it is an extensive carbonate belt that was built up mainly from algal and/or microbial carbonate sediment (Palmer, 1971; Brady and Koepnick, 1979; Aitken, 1997).

It is known that the OMZ existed during the deposition of the Middle-Cambrian Wheeler Formation, and the low oxygen content of the HRE deep water is supported by multiple studies. The uninterrupted lamination of fine-grained shale and flaggy limestone facies, along with the abundance of carbon remains, indicate deposition under quiet and low dysoxic or even anoxic bottom water (Rees, 1986). However, the existence of pelagic agnostoid trilobites indicate that the HRE water was open to the marine currents (Rees, 1986). Also, the preservation of suspension laminae and the rare occurrences of unidirectional marks such as current-oriented fossils, and

sole and tool marks, suggest deposition under quiet and poorly oxygenated water within the OMZs (Rogers, 1984; Elrick and Snider, 2002). The abundance of organic preservation of nonmineralized macrofossils through meters-thick-intervals indicates the prevalence of anoxic events during the deposition of much of the Wheeler Formation (Gaines and Droser, 2003; Gaines et al., 2005). The opportunistic trilobite, Elrathia kingii, is observed in a few localities in the Middle-Cambrian Wheeler Formation where it inhabits the exaerobic zone; the boundary between dysoxic and anoxic deep-water zones (Savrda and Bottjer, 1987; Gaines and Droser, 2003). Burgess Shale-type deposits that contain well preserved assemblages of soft-bodied and nonmineralized fossils, *konservat-lagerstatten,* have been observed in the middle and upper Wheeler Formation in the House Range and Drum Mountains (Gaines et al., 2005; Halgedahl et al., 2009). This exceptional preservation is known to occur in low-energy dysoxic or anoxic deep water at maximum sea level rise, where low permeability clay-rich layers are deposited within a well-developed OMZ (Gaines et al., 2005; Halgedahl et al., 2009). A similar clay-rich, carbonate-poor interval is observed within the lower Wheeler Fm. above the base of the Drumian Stage (CP7, Figs. 3 and 4; Chapter-I). The Maximum DICE excursion is observed very close to this interval in the GSSP and Packrat sections.

Clearly, HRE slope and basinal areas were affected by poorly oxygenated deep water because they represent the inward extension of slope and basinal areas of the passive margin of western Laurentia (Rees, 1986). Carbonate isotopic values depend on the source of carbonates in the sections studied here. Carbonate sediments that originated in the well-oxygenated shallow water of shelf and upper slope areas, have heavier $\delta^{13}C$ and $\delta^{18}O$ values than those that originated close to or in the OMZ in downslope and trough areas. The latter refers to the pelagic carbonate

particles that are formed and deposited within the ^{12}C-rich HRE water. The DIC of HRE deep-water is expected to have much lower $\delta^{13}C$ values than the DIC of near-by shallow, well oxygenated, northern-platform water. Therefore, HRE-sourced carbonates are affected by the respiration and remineralization of organic matter, and their $\delta^{13}C$ and $\delta^{18}O$ are shifted toward lighter, more negative values than are northern-platform-sourced carbonates.

The onset of the DICE depends on the, 1) depth and location of each locality, 2) sea level, and 3) circulation pattern within the HRE. Shallow localities that are very close to the HRE northern edge, are flooded with carbonates that have heavier $\delta^{13}C$ and $\delta^{18}O$ than downslope and deep trough localities that are far from the HRE edge. As sea level rises, the OMZ gradually encroaches into the HRE toward the northeast, parallel to the HRE trough. Respiration and remineralization are initiated when the given locality is encroached upon by the organic matter included within the OMZ. Once the DICE is initiated, $\delta^{13}C$ continues to decrease as the OMZ gradually approaches each locality. The $\delta^{13}C$ decrease continuum is disturbed and suppressed by either rapid sea level falls or storm events. $\delta^{13}C$ is observed to increase during these circumstances because the HRE is flooded by isotopically heavier platform carbonates that are formed under shallow, well-oxygenated water. Turbidity currents carry the agitated sediments during storm events, and surface water currents deliver platform carbonate sediments to the HRE during times of sea level fall. This is aided by the carbonate factory advance over the HRE edge (Elrick and Snider, 2002).

The isotopic difference between storm layers and the containing sediments above the base of the Drumian Stage depends on the location of each section. This difference is less prominent in lower slope sediments of the southern ramp (Packrat),

and shallow sections that are close to the northern platform (GSSP section), because storm derived sediments are sourced from close-by areas that exhibit similar isotopic values (Fig. 3.6). However, this is more prominent in lower-slope sections of the northern ramp (Marjum Pass section), because storm sediments conserve their original isotopic signal down to deep dysoxic or anoxic water (Fig. 3.6). At the GSSP section, the storm layers and the containing sediment originated from the same shallow areas and were delivered over short distances, either by shelf currents that deliver the containing sediments or by storms as storm deposits. In the Packrat section, sediments were either eroded from areas that experienced dysoxic conditions, or were delivered by exhausted turbidity currents. These turbidity currents weakened as they move downslope, and the included sediments are buried within other $\delta^{13}C$ depleted sediments. In the Marjum Pass section, these storm deposits were formed in shallow well-oxygenated shelf water and then delivered to slope and basinal localities where the containing sediments were formed in the deep, poorly-oxygenated water of the HRE. As a consequence, the Marjum Pass section was isotopically more sensitive to facies changes than were the other two sections. In addition, the negative $\delta^{13}C$ excursion was likely dampened due to incoming, isotopically-heavy, carbonates (storm deposits). Given that the Marjum Pass section has its maximum negative $\delta^{13}C$ excursion, DICE, below the base of the Drumian Stage, while the other two sections have their maximum negative $\delta^{13}C$ excursion, DICE, ~10 m above the stage boundary (Fig. 3.6).

It is argued here that the Marjum Pass DICE event, which lies at 1 m below the base of the Drumian Stage, represents an Apparent DICE (A-DICE – Fig. 3.6) where the actual DICE is located 6 m above the base of the Drumian Stage, at ~30 m above the base of the Wheeler Formation (Fig. 3.6). This actual DICE was

probably suppressed by incoming, isotopically-heavy carbonates that were delivered to the HRE during the onset of the rapid sea level fall that follow the maximum sea level rise at that time. This Actual Suppressed DICE (AS-DICE) is stratigraphically synchronous with the maximum negative carbon isotope excursion, DICE, events observed in the other two sections. In addition, the AS-DICE coincide with the synchronous *P. atavus* acme in Marjum Pass section and the GSSP (Chapter-II). The interval between the base of the Drumian Stage and the DICE, or AS-DICE, event varies in thickness among the three studied sections due to the sediment accumulation rate (SAR) at each site. Therefore, the DICE event is a viable chronostratigraphic marker that precisely constrains the base of the Drumian Stage regionally in the HRE, however, it was occasionally suppressed by the flux of isotopically-heavy shelf carbonates that were delivered to sites during sea level fall and/or storm events.

3.6. DICE correlation between Laurentian platform and basinal sections

The DICE or AS-DICE anomaly provides a reasonably good chronostratigraphic marker that precisely constrains the base of the Drumian Stage when used along with other high-resolution data sets such as χ and $CaCO_3$% content within the HRE (for more details, see Chapter-I). The DICE in the Middle-Cambrian carbonate platform sections is still enigmatic and its stratigraphic position relative to slope and basinal DICE stratigraphic position is uncertain. The complex lithological relationship between HRE and platform sections, as well as the absence of agnostoid trilobites on the shelf, add more challenges when correlating between basinal and platform sections (Howley and Jiang, 2010).

Those published $\delta^{13}C$ data for the DICE interval on the southern Laurentian carbonate platform (Howley, 2010; Howley and Jiang, 2010) are used here for

comparison. This data set represents three southern platform sections (Wah Wah, Panaca Hills and Desert Range). Sparry cement samples, most sample replicas, and the individual data points that show high correlation potential between $\delta^{13}C$ and $\delta^{18}O$ have been removed in figure 3.7 (modified from Howley, 2010; Howley and Jiang, 2010). The height of each section is adjusted to the closest formations or members boundary. The base of the Papoose Lake/Banded Mountain members boundary, Medow Valley/Condor members boundary, and Eye of Needle Limestone/Pierson Cove Formations boundary are held as three stratigraphic datums for Desert Range, Panaca Hills, and Wah Wah sections, respectively (Fig. 3.7). These data, along with our high-resolution data set, are used to assess Laurentian platform to basin correlation. This work also aims to provide a reasonable explanation for the existence of the DICE on carbonate platform sections (Figs. 3.6 and 3.7).

The platform-to-basin $\delta^{13}C$ data sets are presented in figures 3.6 and 3.7. DICE thickness is observed to change through these six sections. In slope and basinal sections, the DICE thickness is highest close to the HRE mouth and decreases in the northeasterly direction as the width and depth of the HRE decreases (Fig. 3.6). Even though, the Packrat section doesn't cover the entire DICE interval, it is clear that it has the highest DICE thickness because the interval over which $\delta^{13}C$ decreases to its minimum is about three times its equivalent in the Marjum Pass section (Fig. 3.6). DICE records its lowest thickness in the GSSP section, although it was reported to be an expanded section and have high SARs (Babcock et al., 2007; Howley and Jiang, 2010) (Fig. 3.6). In the southern platform sections, the DICE thickness is observed to decrease away from the HRE from Wah Wah through Panaca Hills to Desert Range sections (Figs. 3.1 and 3.7). Even

though the DICE increasing limb in Desert Range section is poorly represented, the thickness of the DICE decreasing limb is observed to decrease away from the HRE (Fig. 3.7). In summary, DICE thickness decreases away from the HRE mouth in slope and basinal sections, and away from the southern edge of the HRE in southern carbonate platform sections.

Circulation pattern, sea level changes, and paleogeographic configuration are the factors that account for the existence of DICE on the carbonate platform when the OMZ was well developed in slope and basinal areas around the base of the Drumian Stage. Ocean surface currents that were driven by the trade winds, likely drove the HRE poorly-oxygenated, $\delta^{13}C$-depleted water to the southern carbonate platform. This water imprinted the platform carbonates with low $\delta^{13}C$ and $\delta^{18}O$ values due to respiration and remineralization of included organic matter. This hypothesis is supported by, 1) the upwelling of HRE deep dysoxic water that is known to increase during sea level rise (Howley and Jiang, 2010), and 2) the Coriolis Effect that deflects northeastward moving HRE bottom water to the right, southward, parallel to trade winds direction.

The HRE paleogeographic configuration helps the surface currents to drag the ^{12}C-rich, poorly-oxygenated HRE water to the southern carbonate platform where it mixes with the platform well-oxygenated water. The HRE is a fault-controlled embayment that cuts through the Laurentian carbonate platform and extends more than 400 km in the northeasterly direction, perpendicular to the trade wind direction (Rees, 1986) (Fig. 3.1). Because the OMZ rises close to HRE edges during maximum sea level rise, mixing occurs between the poorly oxygenated organic rich the HRE deep water and well oxygenated surface water. The mixing ratio increases during sea level rise and peaks and is expected to peak at maximum sea level rise

and records the DICE maximum negative excursion in all platform sections. It is likely that this ratio decreases southward away from the HRE due to additional mixing with the southern platform shallow water. The DICE minimum $\delta^{13}C$ values are likely to be synchronous within the embayment and platform sections. The Marjum Pass section is an exception because the actual DICE is suppressed by incoming heavier isotopic-value carbonates. High-resolution χ, Total Organic Carbon (TOC), and $CaCO_3$% content analyses make it possible to examine the extent to which OMZ is elevated during maximum sea level rise across the platform DICE.

The absence of $\delta^{13}C$ depleted values within the GSSP carbonate-dominated intervals at the time when it is recorded within the Marjum Pass and the Packrat section, explains DICE absence in northern platform sections (Fig. 3.6). These carbonates are shed off the northern carbonate platform by shelf currents that were driven by trade winds, and flooded sections that were close to the HRE northern edge during carbonate factory progradation and sea level fall (Chapter-I; Elrick and Snider, 2002). Accordingly, the DICE interval is expected to shrink even more within HRE sections that are very close to the northern edge. Because DICE can be easily missed in these sections, high-resolution sampling is required when the DICE is targeted. However, the DICE is recorded within the carbonate-dominated southern platform sections because the paleogeographic configuration of the embayment allowed HRE $\delta^{13}C$ depleted water to be dragged over the southern platform by the same shelf currents and therefore imprint their isotopic signal.

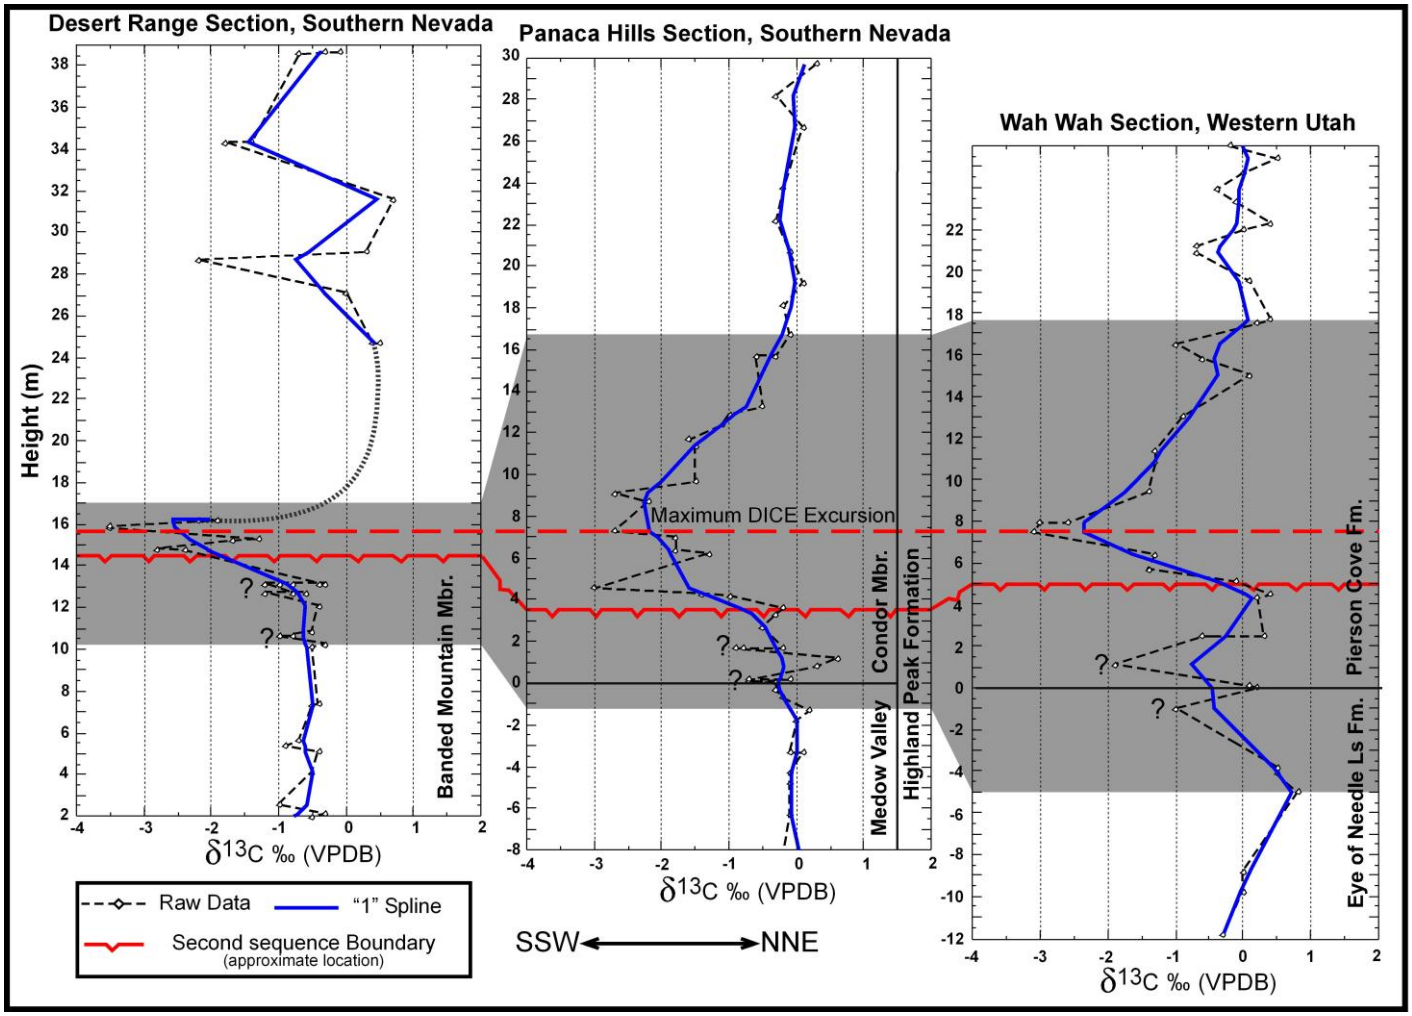

Figure 3.7. Three curves showing high-resolution correlation among the platform sections; Wah Wah, Panaca Hills and Desert Range, data modified and redrawn from Howley (2010) and Howley and Jiang (2010). The DICE range is expressed as grey shaded boxes that are correlated among the three sections. In addition, the DICE maximum excursion and the second unconformity are also represented.

3.7. The base of the Drumian Stage on the Laurentian carbonate platform

The basal boundary of the Drumian Stage is placed at the base of the first of three storms layers in slope and basinal sections (Chapter-I). This boundary marks an erosional surface that lies below the maximum negative $\delta^{13}C$ excursion, DICE, at the GSSP section. The GSSP is reported to be a shallow trough section that is very close to the carbonate platform edge (Chapter-I). The high-energy turbidity currents that were initiated by the first storm event accounts for the formation of the Drumian eroded base. It was driven by the seafloor slope-angle and the density difference between the current and surrounding HRE seawater (Chapter-I). It is expected that the same storm event should have created a synchronous, more intensive, erosional surface on the carbonate self below the maximum negative $\delta^{13}C$ excursion, DICE minimum $\delta^{13}C$ values. Multiple erosional surfaces, including the second sequence boundary, have been observed below the DICE in the southern carbonate platform sections (Howley and Jiang, 2010), where the three storm deposits are observed in the HRE sections. Any of these erosional surfaces is likely to represent the base of the Drumian Stage. Because both the base of the Drumian Stage and the maximum negative $\delta^{13}C$ excursion are synchronous in the HRE and platform sections, the interval between them fluctuates among all sections depending upon the SAR. While HRE results are based on high-resolution sampling, this has not been performed on southern platform sections. Therefore, high-resolution correlation is needed to determine which erosional surface in the southern platform sections represents the base of the Drumian Stage.

Tracing the base of the Drumian Stage to an erosional surface on the southern carbonate platform of the HRE is supported by multiple arguments. First, it is placed at an erosional surface in the GSSP section. Second, multiple erosional

surfaces have been reported below the maximum DICE excursion in southern platform sections (Howley and Jiang, 2010), while three storm deposits are observed below this maximum excursion in HRE sections (Chapter-I). Third, the first storm event is expected to be strong enough to produce an extensive erosional surface, which might have produced lag deposits on the carbonate platform because the turbidity current delivered calcisiltite sediments to the GSSP section. In addition, the first storm layer is observed in the Packrat section where the two succeeding storm layers are either diminished or were not deposited at all (Chapter-I). Even though some grainstone/packstone lag deposits are observed associated with platform erosional surfaces (Howley and Jiang, 2010), more petrographical work is needed to identify those lag deposits within or slightly below the DICE event.

3.8. Regional to global DICE correlation

The DICE signal marks a global event because the DICE is observed in the platform and slope sections in northern and southern China (Zhu et al., 2004). In the Wangcun slope section in China, a negative $\delta^{13}C$ excursion starts within the Aoxi Formation and reaches its minimum values within the lower member of the overlying Huaqiao Formation (Fig. 8 modified from Zhu et al., 2004). In addition, the LOOP of *P. atavus* there marks the base of a $\delta^{13}C$ increase that coincides with a lithological change (Fig. 3.8). The associated facies and $\delta^{13}C$ signal are similar to those found in HRE sections. The facies changes in the Wangcun section begin with black shale with increasing amounts of dark gray, thin-bedded limestone interbeds, changing to dark gray, thin-bedded limestone, that lacks black shale interbeds, close to the LOOP of *P. atavus* (Peng et al., 2004) (Fig. 3.8).

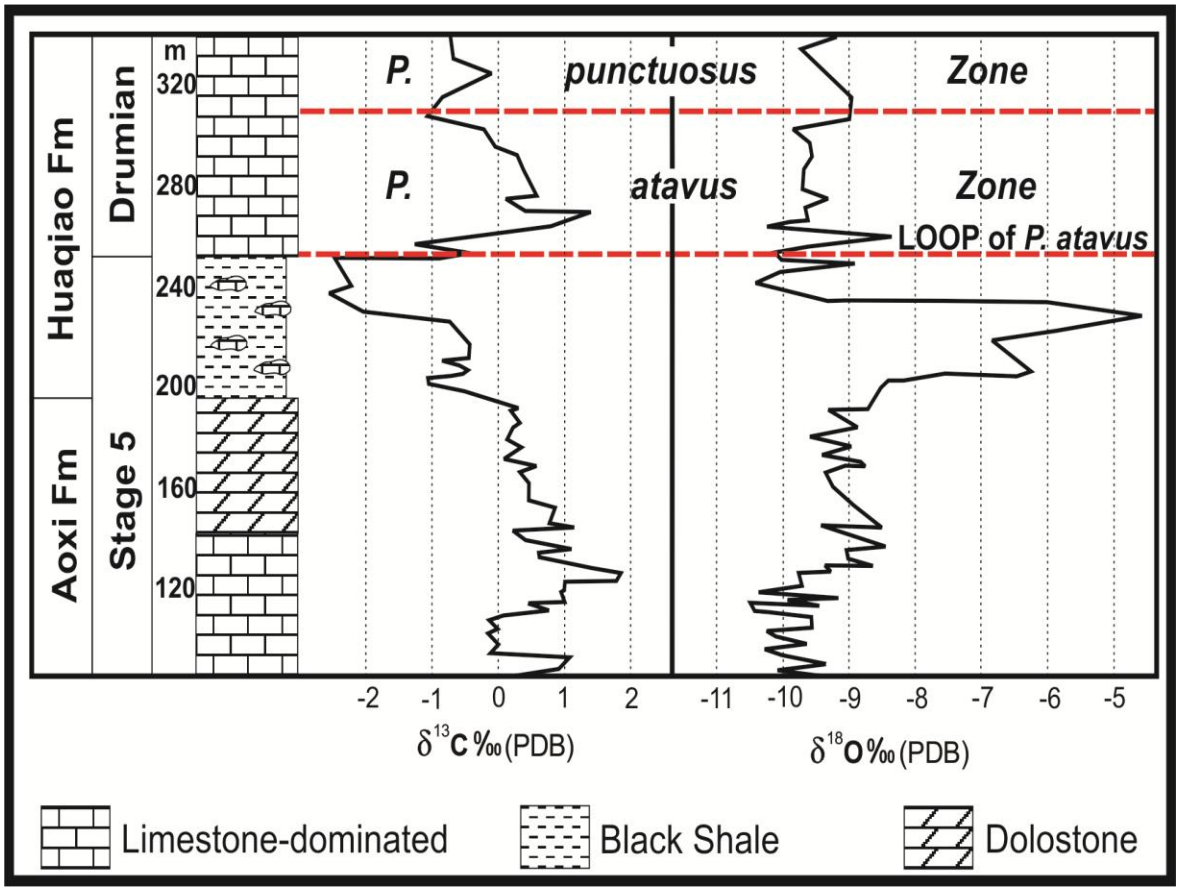

Figure 3.8. Chemostratigraphic diagram of the Middle-Cambrian Wangcun section, western Hunan Province, China showing $\delta^{13}C$ and $\delta^{18}O$ data, and the associated facies and bizones (modified from Zhu et al., 2004). The Lowest Observed Occurrence Point (LOOP) of *Ptychagnostus atavus* lies at the base of a carbonate-rich interval where $\delta^{13}C$ increases rapidly to reach pre-DICE levels. The Maximum DICE excursion is observed within a clay-rich interval, at the base of the carbonate-rich interval. This signal is similar to its counterpart in HRE sections.

In HRE sections, $\delta^{13}C$ decreases to reach its minimum within detrital-dominated facies, and increases within carbonate dominated facies. In addition, regional lithofacies and sedimentary pattern studies reveal that the broad, extensive Yangtze carbonate platform gave way to an ocean-facing-slope and poorly-oxygenated deep-water basin (Peng and Babcock, 2001). Consequently, the factors that account for the DICE existence in the platform and basinal sections of western Laurentia, likely held true for its existence on the platform and slope sections of south China region. High-resolution χ, $CaCO_3$%, and chemostratigraphic analyses are needed to confirm this hypothesis.

3.9. The DICE Model

The DICE model provides an explanation for the existence of DICE in HRE and platform sections of western Laurentia (Fig. 3.9). This model assumes, 1) the existence of a well-developed, organic-rich, OMZ across the base of the Drumian stage during a time of sea level rise, and 2) that the trade winds were the main driver of surface currents over the Laurentian carbonate platform. The existence of the OMZ and trade winds during the deposition of the Middle-Cambrian Wheeler Formation is supported by multiple studies (Rogers, 1984; Rees, 1986; Savrda and Bottjer, 1987; Elrick and Snider, 2002; Gaines and Droser, 2003; Gaines and Droser, 2005; Gaines et al., 2005; Halgedahl et al., 2009; Howley and Jiang, 2010).

During lowstand, HRE and platform water masses are considered as one water mass that is driven by northerly (using today's coordinates) trade winds (Fig. 3.9, stage 1). Therefore, the HRE was covered by shallow, well-oxygenated water where isotopically heavy, carbonate-dominated facies were formed. During sea level rise, the organic-rich OMZ encroached the HRE through the HRE mouth and mixed with the well-oxygenated platform water (Fig. 3.9, stage 2). Oxidation of the OMZ organic matter pumped light carbon (^{12}C) into HRE water and produced more $\delta^{13}C$-depleted water than existed in surrounding platform water. Carbonates formed in such an environment were more $\delta^{13}C$ depleted than those formed in a shallow, isotopically heavy northern platform environment.

The paleogeographic configuration of the HRE, being perpendicular to surface currents directions, and the upwelling that increased during sea level rise, expedite this process. Consequently, the negative $\delta^{13}C$ excursion is proportional to the degree of respiration and remineralization of the organic matter. During maximum sea level rise, maximum respiration occurs because the OMZ rises to its highest level at or

close to HRE edges (Fig. 3.9, stage 3). It is likely that the maximum negative $\delta^{13}C$ excursion occurs during this interval. These three steps are expected to have reversed and mark $\delta^{13}C$ increases during subsequent sea level falls.

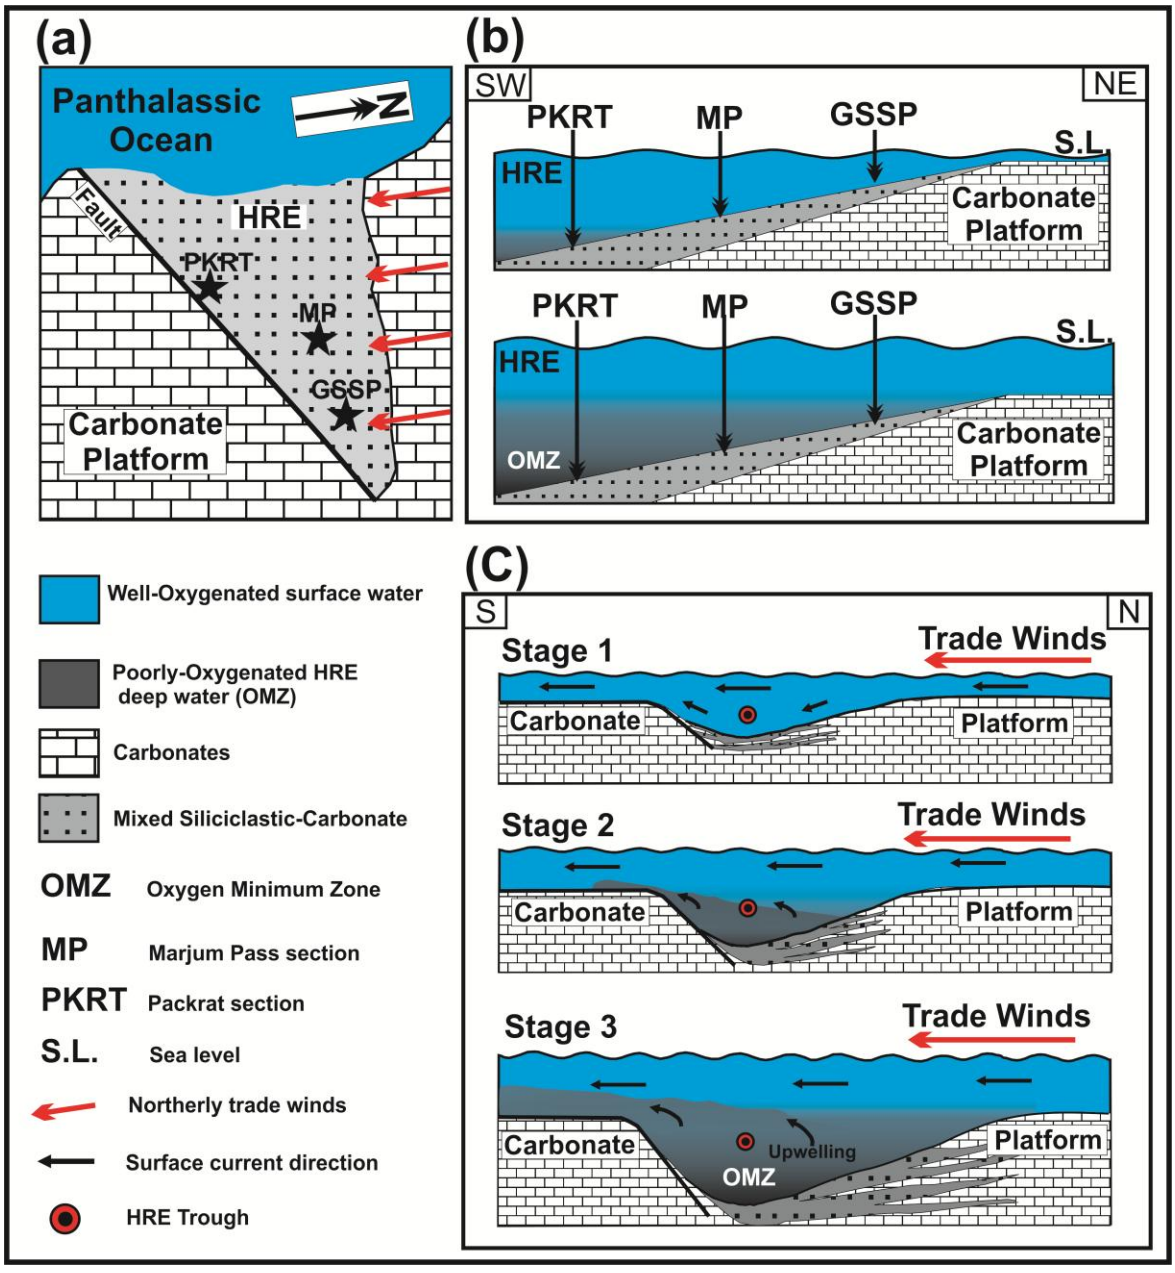

Figure 3.9. Hypothetical model illustrating the formation of the DICE interval in HRE and Platform sections of western Laurentia. The red dots represent the HRE trough. Both sea level and water depth increase from stage 1 to 3. The light blue color represents the shallow well-oxygenated water. The dark grey color represents deep, poorly oxygenated HRE water. The middle bright blue color represents mixed water from the two water-mass end members. Arrows show the direction in which shallow and deep-water masses move.

In HRE sections, the DICE starts when the locality is encroached upon by $\delta^{13}C$ depleted water, then maximizes at the point of maximum sea-level rise, where maximum respiration occurs, and ends during the subsequent sea-level fall when the OMZ abandons the locality, and $\delta^{13}C$-depleted water is replaced by $\delta^{13}C$-enriched water. In platform sections, $\delta^{13}C$-depleted water from the HRE is driven to the southern platform by surface currents and imprinted the platform carbonate with low $\delta^{13}C$ values. Therefore, the maximum DICE excursion is likely to be synchronous in the HRE and platform sections because their sites are controlled by the same factors during the maximum sea level rise. However, both the onset and the end of the DICE is observed to be diachronous among the studied sections when high-resolution correlation is applied. Because the depth and width of the HRE decreases in the northeasterly direction, the OMZ and $\delta^{13}C$-depleted waters encroach and/or abandon different localities at different times during sea level rise and/or fall. In addition, the DICE signal is sporadically suppressed during storm events because storms erode and deliver northern platform $\delta^{13}C$-rich carbonates to HRE $\delta^{13}C$-depleted carbonates. Thus, it is inferred here that the OMZ was well-developed within the slope and basinal areas of the shelf margin of western Laurentia and either, 1) short-lived only across the base of the Drumian Stage, imprinting HRE and southern platform sections during this particular sea level rise over any other sea level rise, or 2), long-lived during the Middle-Cambrian, and sea level rose to an unprecedented level during deposition of the base of the Drumian Stage, elevating the OMZ to unprecedented levels. This, in turn, allowed deep-water mixing with well-oxygenated shallow water, and initiated respiration and mineralization of the included organic matters. To examine which of these two hypotheses accounts for the global existence of the DICE event, high-resolution correlation among intervals of similar

depositional environments within the Wheeler Formation is required. Halgedahl et al. (2009) reported a similar clay-rich, carbonate-poor, interval in upper Wheeler Formation sediments, at ~230 m from its base. They called this interval the “hot zone” because it had exceptional preservation potential. The SAR in this “zone” indicates that it is more expanded than is the Drumian GSSP interval. In addition, it is also preceded by three carbonate layers that are similar to the three lower Wheeler Fm. storm layers.

3.10. Conclusions

The DICE is a chronostratigraphic marker that constrains the base of the Drumian Stage in the House Range Embayment (HRE) and surrounding southern carbonate platform sections. The DICE maximum excursion point should be used for correlation among Laurentian sections because it marks the maximum sea level rise after the base of the Drumian Stage. However, the onset and the end of the DICE are diachronous among the studied sections, and should not be used for stratigraphic correlation between multiple localities when high resolution is desired. The GSSP section provides the most practical example of the diachronicity of the DICE. The DICE in the GSSP section starts later and ends earlier than at other sections. Also, the GSSP is the last locality that was encroached upon by the Oxygen Minimum Zone (OMZ) during sea level rise, and the first to be abandoned during sea level fall. Consequently, the GSSP DICE covers a smaller interval than its equivalent in other sections. The location of the GSSP section dictates this effect. It is a shallow trough section that is flooded by heavier-isotopic carbonates during storm events, sea level fall, and early stages of sea level rise, while the other two HRE sections studied here reside in deeper poorly oxygenated, $\delta^{13}C$-depleted, water.

The maximum DICE excursion is observed only at maximum sea level rise that follows the base of the Drumian Stage in the HRE and the platform sections, unless occasionally suppressed by the incoming heavier-isotopic carbonates. Marjum Pass section provides a case for DICE suppression, where carbonate-dominated storm layers shift $\delta^{13}C$ signal temporarily toward heavier values.

The DICE is interpreted to result from respiration and remineralization of organic matter that is included in the OMZ. This process pumps light carbon into the HRE water mass and accounts for $\delta^{13}C$ depletion within the HRE and platform sections. It is inferred that the OMZ was well-developed, either 1) only across the base of the Drumian Stage and imprinted HRE and southern platform sections only during the sea level rise that occurred when the FAD of *P. atavus* also occurred, or 2), during the Middle-Cambrian, and sea level rose to an unprecedented level at the Drumian Stage FAD, elevating the OMZ to unprecedented levels. The DICE is observed on the southern platform because HRE poorly oxygenated, ^{12}C-rich deep water was dragged across the carbonate platform by surface currents that were driven by the trade winds. As a result, the base of the Drumian stage is expected to lie at the base of one of several erosional surfaces that lie below the maximum negative $\delta^{13}C$ excursion on the southern carbonate platform that were observed by Howley (2010). In addition, the DICE interval is likely to shrink in sections that are close to the HRE northern edge and disappear within the northern platform sections.

RECOMMENDATIONS

It is recommended that samples from other sections, which are distributed within the house range embayment be collected. The targeted sections should cover a longer interval, with the aim of tracing the lithostratigraphic markers, including storm layers, throughout the rest of the HRE. The goal would be to obtain facies distribution of these sediments and to differentiate between normal and storm deposits in an interval that is characterized by tectonic quiescence (Howley, 2010). This would demarcate the down-slope reach of the storm deposits, and hence, the limits of the reworked *P. atavus* specimens. It is concluded in this dissertation that the storm sediments are likely absent or have negligible thicknesses in the downslope sections of the northern ramp. Therefore, they represent better alternative successions to the current GSSP section. Unlike the three studied, syndepositional structures, erosional surfaces, and reworked sediments is expected to be at their minimal because their long distance from the northern HRE edge and small slope angle. In addition, they are expected to have high sediment accumulation rates of detrital dominated facies that assure event separation and have less lithological variations than the studied sections. Moreover, the DICE is expected to have more conspicuous signal and cover longer interval. These conditions are met on the southwest part of the embayment where the HRE has its maximum depth and width, and the fault had its maximum displacement. Steptoe Ranch in northern Egan Range (nEs), Muncy Creek in Northern Schell Creek Range (nSCm), Radio Tower in southern Egan Range (sE), and Patterson Pass in southern Schell Creek Range (sSC) are recommended successions for future studies (Figs. 2, 3 and 5; Rees, 1986). Intensive search for *P. atavus* and stable isotope analysis, $\delta^{13}C$ and $\delta^{18}O$, are recommended along with χ and

$CaCO_3$ to establish high-resolution regional chronostratigraphic correlation. This correlation can be extended globally to the Wangcun section in China because it has remarkable similarity with the studied sections. In conclusion, the depositional environment differences should account for χ, $\delta^{13}C$ and $CaCO_3$% variations among these sections.

APPENDICES

Tabulated below are the mass-specific magnetic susceptibility (χ), carbonate contents ($CaCO_3$%), and stable isotopes ($\delta^{13}C$ and $\delta^{18}O$) measurements and their splines for the Global Boundary Stratotype Section and Point (GSSP) of the base of the Drumian Stage that have been placed on Stratotype Ridge (39°30.705´ N, 112º59.489´ W) in the Drum Mountains, western Utah (Babcock et al., 2007), and two equivalent marine sedimentary successions. The equivalent sections are (1) the Marjum Pass section that was collected at the House Range (39°14'30.13" N, 113°22'30.61" W), western Utah, and (2) the Packrat section that was collected along the North Fork of the Big Wash (38°54’00.63926” N, 114°13’25.05219” W), Great Basin National Park, southern Snake Range, White Pine County, eastern Nevada. These data sets cover an interval that includes the Middle-Cambrian upper most part of unnamed Stage Five and the lowermost part of the Drumian Stage in the House Range Embayment (HRE). The height was adjusted to the closest formations boundary, the base of the Wheeler Formation at the GSSP and the Marjum Pass sections, and the base of the Lincoln Peak Formation at the Packrat section.

4.1. Mass-Specific Magnetic Susceptibility (χ) Measurements

4.1.1. The GSSP section, Drum Mountain, Western Utah

4.4. Carbonate Digestion Apparatus

4.4.1. Theoretical background

Carbonate digestion is a method that has been used to quantify the carbonate content, in percent (%), within any sediment or sedimentary rock sample. Carbonate rocks constitute 20-25% of the sedimentary rock record, and are observed in all stages, series and systems of the Phanerozoic. Limestone and dolomite constitute the majority of the carbonate sedimentary rock record. They might be pure or mixed. Pure carbonate rocks are rare and are composed entirely of carbonates (100%). Mixed carbonate rocks are abundant and have different carbonate percentage that ranges between 0 and 100%. Carbonates are mixed with non-carbonate sediments, primarily siliciclastic sediments. Carbonates might be deposited simultaneously along with siliciclastic sediments in the same depositional environment or serve as cement. Quantifying the carbonate content along with other geochemical and/or geophysical analyses of patterns in collected samples help to construct facies analysis models. These models lead to depositional environment interpretations, and decipher lateral and vertical lithological variations when correlated to time equivalent sections. This unravels stratigraphic complexity and can provide an insight into entire marine sedimentary basins.

This manual illustrates the carbonate digestion method when the vacuum-gasometric technique (Jones and Kaiteris, 1983) is used. First, 0.25 gm of powdered sample is allowed to react with 5 ml of highly concentrated phosphoric acid in a closed system. This reaction releases carbon dioxide gas, where

$$3CaCO_3 + 2H_3PO_4 \rightarrow Ca_3(PO_4)_2 + 3H_2O + 3CO_2 \qquad (1)$$

Because the reaction is performed in a closed pre-vacuumed system, the change in system pressure, ΔP, quantifies the released CO_2 gas. This change represents the

difference in pressure before and after the reaction. The carbonate percent is calculated when ΔP of a given sample is compared with the ΔP of a standard sample. A correction should be made for the volume differences between different reaction vessels. Three different cases have been observed throughout thousands of measurements;

1. If the given sample has no carbonates, its ΔP equals zero and its carbonate percent equals 0%.
2. If the given sample is composed of pure carbonate, its ΔP equals the ΔP of the standard sample and its carbonate percent equals 100%.
3. If the given sample has different contribution of carbonates and non-carbonate materials, its' ΔP and carbonate percent lie in between the upper two cases.

The third case is more common for fine grained marine sedimentary rocks than the first two cases.

4.4.2. Apparatus Components (see the appendecies figure below):

1- Reaction Vessels (RV): It has a main tube and side arm. Each reaction vessel has its own number.

2- Reaction vessel cap (RV cap): It has a valve that is referred to as the "RV cap valve". Each RV cap has a number that matches its corresponding reaction vessel.

3- O-rings and clamps: Used to attach the RVs with their caps. The O-rings should always be greased before use.

Note: All the above-mentioned parts can be assembled into one entity which is referred to as the **RV assembly**.

4- Reaction vessel rail: Holds all RVs and RV caps during measurements.

5- Vacuum meter: Measures the system pressure

6- Vacuum Pump: Pumps the air out of the system before the reaction starts. It also pumps the system down before releasing the CO_2 into the system.

7- System valve A: Connects the system with the vacuum pump.

8- System Valve B: Connects the system with the RV assembly through the system outlet.

9- System Outlet: Connects the system with the RV assembly

10- Electric vibrator: used for sample agitation.

4.4.3. Testing the system

1. Turn on the vacuum pump and the vacuum meter, open system valve A, and close system valve B.
2. Leave the pump on for ~5 minutes to equilibrate. Close system valve A, turn off the Vacuum pump and watch the vacuum meter.
3. Be sure that A and B valves are closed properly.
4. The pressure should increase slowly. If the pressure increases rapidly, then the system has a leak that should be fixed before use.

4.4.4. Sample Preparation

1. Grind ~1 gm of each rock sample to pass a ~63µ screen, using a pestle.

   Note: This increases the reaction surface area and reduces the chances of any leftover carbonates during reaction.

2. Place the powdered sample in a cupcake holder on an electric heater griddle, for one hour at ~110^{o} C.

   Note: This step removes the moisture and reduces sample weight errors. You can leave the sample on the griddle for a longer time at a lower temperature.

This apparatus consists of eight reaction vessels. Therefore it is preferred to prepare eight, or more, samples at a time.

4.4.5. Sample Measurement

1. Carefully add 0.25 gm of the dried sample into the main tube of the reaction vessel.

   Note: Place the RV on the scale and zero its weight. Then carefully add the 0.25 gm using a spatula. Be sure that the RV is cleaned properly.

2. Add 5 ml of phosphoric acid into the RV side arm using a pipette. Don't spill any acid on the sample in the main RV tube.
3. Grease the O-ring and use it to attach the RV with its cap. Clamp them together and tighten the clamp screw tightly.

   Notes:

   I. The RV number should always match the RV cap number.

   II. The RV side arm and the cap valve outlet should be on the opposite sides, at 180^{o} angle, during assembly (Fig. 1C).

   III. Don't tilt the RV assembly or it will start the reaction early.

4. Attach the RV cap male outlet to the system female inlet with the small O-ring in between.

   Notes:

   IV. Be sure that the small O-ring is in place and greased.

   V. Hold the RV assembly firmly against the system inlet.

   VI. Be sure that the RV cap valve is **OPEN**.

5. Turn on the Vacuum pump and the vacuum meter, and open system valves A and B. Let the system adjust for one minute.

6. Close the RV cap valve and system valve B and remove the RV assembly from the system inlet
7. Start the reaction by tilting the RV assembly enough to pore all the acid into the main tube. Then place it onto the RV rail.

   Note: The RV rail slot number should match the RV and RV cap numbers.
8. Leave it there for one and half (1.5) hours and shake it every half hour using the electric vibrator.
9. Connect the RV assembly after 1.5 hours to the system again and pump the system down for one minute. During this step:

   I. System valves A and B must be **OPEN**.

   II. The RV cap valve must be **CLOSED**.
10. **CLOSE** system valve **A** and record the vacuum meter reading.
11. **OPEN** the RV cap valve to release the CO_2 into the system and record the vacuum meter reading.
12. Take the RV assembly off the system inlet, disassemble and carefully clean the RV.
13. Start over for the next set of samples.

4.4.6. Overall Notes:

i. Turn off the meter and the pump after step 7, during the 1.5 hour reaction period.

ii. When it says open or close a certain valve (s), be sure that it is done properly.

iii. During steps 9-11, the RV assembly should always be held firmly against the system inlet.

This apparatus consists of eight reaction vessels. Therefore it is preferred to break the 13 steps of sample measurement into five sets. Each set of steps should be performed for the eight RVs before moving to the next set of steps.

- Set 1 includes steps 1 to 3
- Set 2 includes steps 4 to 7
- Set 3 includes step 8
- Set 4 includes steps 9-11
- Set 5 include steps 12 and 13

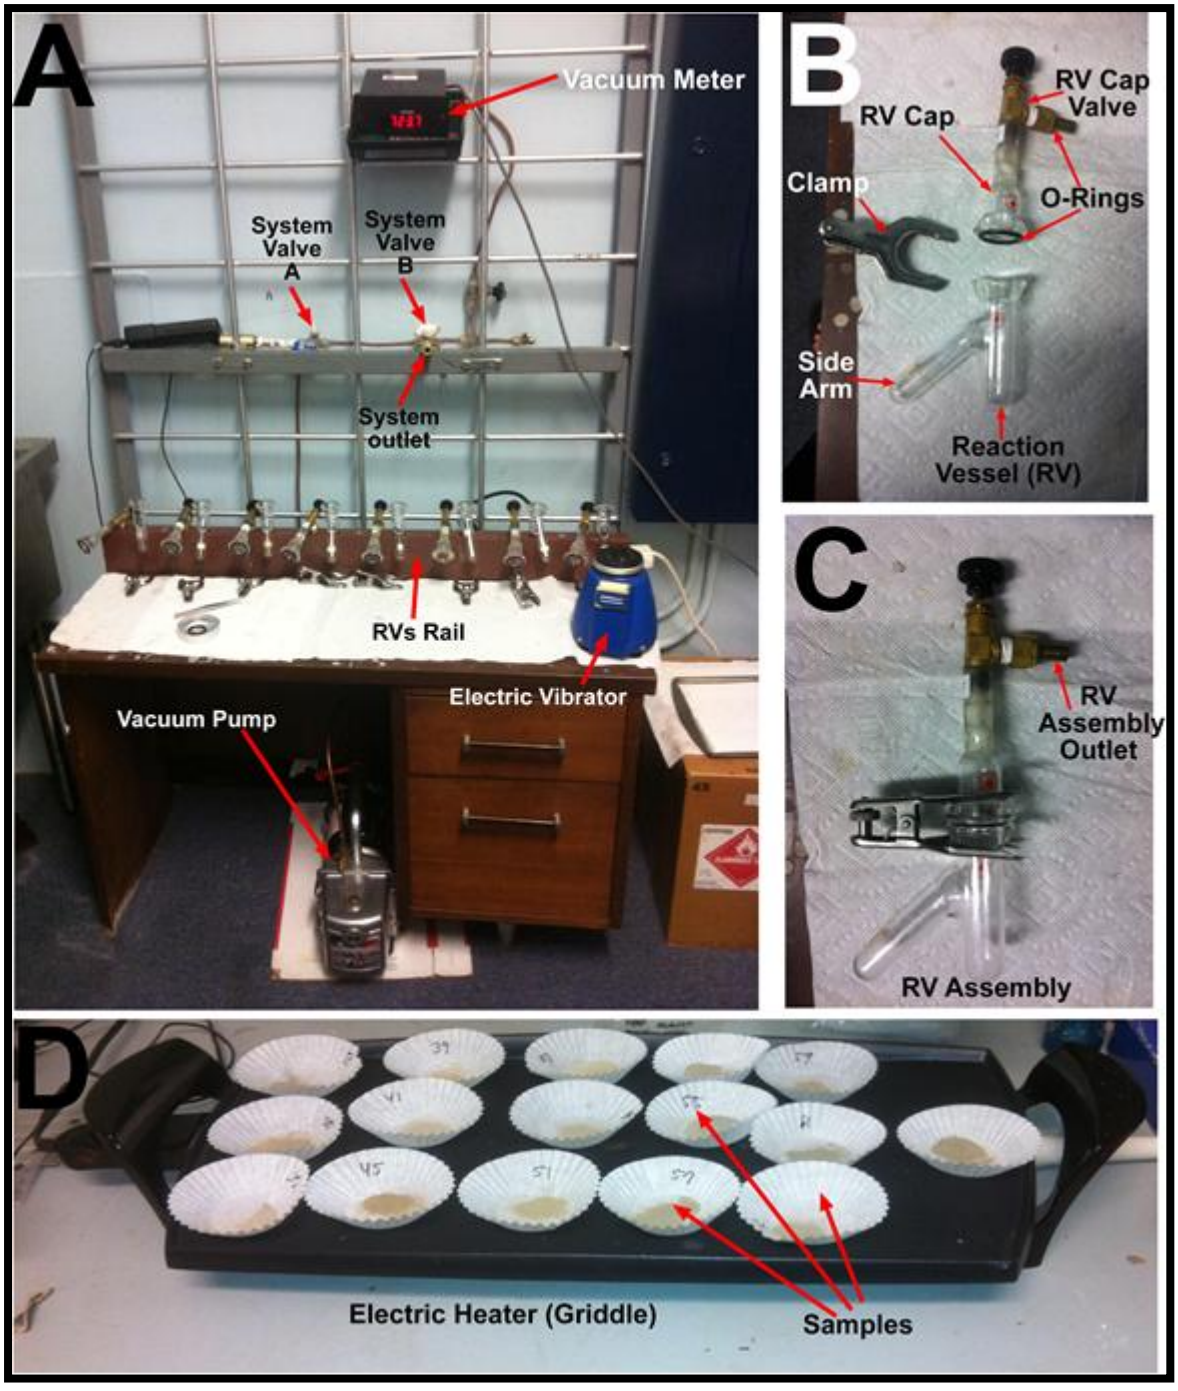
4.4.7. Carbonate Percent ($CaCO_3$%) Calculations

The difference between the two vacuum meter readings in steps 10 and 11, ΔP, represents the CO_2 gas pressure released by the reaction. ΔPs are calibrated for the volume difference among the eight RVs in the final $CaCO_3$% calculations. The carbonate percent final calculation for each sample incorporates ΔP of the measured sample and ΔP of the standard sample for the same RV.

$$CaCO_3\% = (\Delta P_{sample} / \Delta P_{Standard}) \times 100 \qquad (2)$$

The standard ΔP for each RV assembly is tabulated below. It is obtained through running pre-prepared samples of known carbonate percent (standards) for each RV assembly. The $CaCO_3$% values for these samples are 10, 40, 60, and 90 percent of $CaCO_3$. The 100% percent was calculated for each of the four ΔP readings for each RV assembly and the ΔP average is calculated. The standard deviation of these readings is <5, and the ΔP average serves as the standard ΔP for each RV assembly. The $\Delta P_{Standard}$ for every RV is tabulated below.

RV #	ΔP Standard	RV #	ΔP Standard
1	470.4791667	5	450.3472222
2	485.2083333	6	477.6180556
3	480.6041667	7	476.875
4	484.0416667	8	500.2083333



Appendecies Figure: Please email me: emaddelfarr@gmail.com or Dr. Ellwood: ellwood@lsu.edu if you want to build or use this apparatus.

VITA

Emad Elfar, the world long-awaited baby dinasour, was born in Egypt in 1982. I used to have the highest cumulative grades among my peers throughout my education path starting from elementary school to college. Therefore, Tanta University awarded me a bachler degree, offered me a full-time job, and paid for my graduate studies. I was appointed as teaching assistant and then assistant lecturer for about 10 years. After having my master degree from Tanta Unversity, I decided to pursue my PhD studies at Louisiana State University throught full funded PhD opurtunity from the Egyptian government. I had 4.0 GPA during my PhD program that lasted approximately 4 years. I was interested in geology since high school when the science teacher illustrated the formation and deformation of sedimentary rocks, and how water, oil, and gas were stored and migrated within these rocks. My curiosity drove me into undergraduate and graduate program in geology at Tanta University, and PhD program at LSU.
