Abstract
Achieving the vision of identifying and quantifying cancer-related events and targets for future personalized oncology is predicated on the existence of synthetically accessible and economically viable probe molecules fully able to report the presence of these events and targets in a rapid, and highly selective and sensitive fashion. Delineated here are the design and evaluation of a newly synthesized turn-on probe whose intense fluorescent reporter signature is revealed only through probe activation by a specific intracellular enzyme present in tumor cells of multiple origins. Quenching of molecular probe fluorescence is achieved through unique photo-induced electron transfer (PeT) between the naphthalimide dye reporter and a covalently attached, quinone-based enzyme substrate. Fluorescence of the reporter dye is turned on by rapid removal of the quinone quencher, an event that immediately occurs only after highly selective, two-electron reduction of the sterically and conformationally restricted quinone substrate by the cancer-associated human NAD(P)H:quinone oxidoreductase isozyme 1 (hNQO1). Successes of the approach include rapid differentiation of NQO1-expressing and non-expressing cancer cell lines via the unaided eye, flow cytometry, fluorescence imaging, and two-photon microscopy. The potential for use of the turn-on probe in longer-term cellular studies is indicated by its lack of influence on cell viability and its in vitro stability.

INTRODUCTION
Molecular probes whose fluorescent reporter signal is generated (turn-on probes) by enzyme activation hold great potential for identification, enumeration, and study of living cancer cells—outcomes invaluable for accurate and early diagnoses and optimization of surgical...
and personalized chemotherapeutic treatments.\textsuperscript{2,3} In particular, the successful development of enzyme-activatable probes that can yield rapid, and highly sensitive and selective, reporting of species or events associated with cancer cells\textsuperscript{4–6} will allow for definition of diseased and healthy tissue borders during fluorescence-assisted surgical resection of cancerous tissues and collection of real-time information on tumor cell microenvironment or the pharmacodynamic effect of drugs on specific tumor cells.\textsuperscript{3,5–13} To date, live cancer cell detection with varying degrees of selectivity and sensitivity has been limited to routes employing extracellular or cell-surface protein recognition of a covalently attached component of the probe or reporter.\textsuperscript{3,12,14} However, successful identification of living cancer cells and their type differentiation can be achieved by targeting endogenous, intracellular, cancer-associated enzymes with hydrophobic small-molecule (≤1000 Da), turn-on probes, an outcome not possible with large-molecule, recognition-based probes.

A potentially significant and unexplored route with turn-on probes for diagnostics is that in which selectivity and sensitivity of the target reporting process are controlled by enzymatically stimulated removal of fluorescence quencher from the probe. In particular, this route employs probes whose reporter fluorescence is quenched by photo-induced electron transfer (PeT)\textsuperscript{15} from a covalently attached enzyme substrate. Fluorescence ensues from the reporter upon removal of the quencher substrate by an endogenous, cytosolic, disease-associated enzyme found in diseased cells from a wide range of origins.

NAD(P)H:quinone oxidoreductase isozyme 1 (NQO1)\textsuperscript{16–19} is intimately involved with cancer, as it is a gatekeeper for the 20S proteasomal degradation of the p53, p73\textsubscript{α}, and p33 tumor suppressors\textsuperscript{16} and is present in a diverse group of human tumor cells (e.g., pancreas, colon, breast, lung, liver, stomach, kidney, head/neck, and ovaries) at levels 2- to 50-fold greater than in normal tissue.\textsuperscript{17} Furthermore, NQO1 content/activity in tumor cells is strongly affected by cell life cycle and therapeutic approaches.\textsuperscript{18–20} Importantly, NQO1 is found in the cytosol and catalyzes the strict two-electron reduction of quinones to hydroquinones, making this flavoenzyme an ideal target for prodrug therapies\textsuperscript{21} and pro-fluorophores.

Herein we report the design, properties, and NQO1-specific cellular activation of a first-generation, PeT-quenched fluorescence probe. The turn-on sensor probe readily penetrates the membrane of human cancer cells, because it is hydrophobic, small in molecular weight, and charge neutral. Upon rapid and preferential, two-electron reduction of the quinone quencher subunit of the turn-on probe, an intensely light-emissive reporter results from autonomous removal of the activated quinone subunit. Efficacious PeT quenching of fluorescence prior to subunit self cleavage is ensured by careful selection of the electronic properties of the naphthalimide reporter and quinone quencher. The resulting highly fluorescent, cationic reporter is retained by cells, and it exhibits a strong Stokes shift between its absorption and fluorescence emission maxima due to the push-pull internal charge transfer mechanism associated with the naphthalimide scaffold. Overall, these probe characteristics allow for rapid and enhanced signal-to-background imaging and detection of living cancer cells without the typical requirement of unactivated probe removal from the environment. In total, the pro-fluorogenic probe provides for real-time, highly sensitive and selective human tumor cell analysis and differentiation based on NQO1 content.
RESULTS AND DISCUSSION

Q3NI Probe Fluorescence is Controlled by Photo-induced Electron Transfer (PeT) Quenching

We designed the Q3NI probe to have the fluorescence signal of its naphthalimide reporter\textsuperscript{22,23} quenched via oxidative electron-transfer (OeT) by the covalently attached quinone propionic acid motif, Figure 1A. It was posited that it would be possible to achieve this novel mechanism of reporter quenching by carefully tuning the electronic and optical properties of the quinone OeT quencher and the naphthalimide reporter NI, due to extant naphthalimide reporters that are quenched by reductive electron-transfer (ReT).\textsuperscript{22} The Rehm-Weller equation, Equation 1,

\[ \Delta G_{PeT} = E_D - E_A - \Delta G_{00} - \frac{e^2}{\varepsilon d} \]  

was used to examine possible quinone propionic acid quenchers\textsuperscript{24} and 1,8-naphthalimide reporters, as well as linkers between the OeT quencher and the NI reporter, so as to ensure that quenching is thermodynamically feasible and efficient.\textsuperscript{15} In this equation, \( E_D \) is the redox potential of the donor and \( E_A \) that of the acceptor, \( \Delta G_{00} \) is the energy of the first excited singlet state of the reporter, and \( \frac{e^2}{\varepsilon d} \) is the Coulombic interaction energy of the ion pair, known to be 0.06 eV.\textsuperscript{15} The energy of the first excited singlet state of NI was measured to be 3.06 eV.\textsuperscript{15} From voltammetric measurements, \( E_D \) of NI was determined to be 1.74 V, and \( E_A \) for the quinone propionic acid group of Q3NI was found to be −1.01 V (Figure S2). From these values, the energy change for this OeT process, \( \Delta G_{PeT} \), is calculated to be −0.37 eV, indicating that electron transfer from the excited dye to the electron-poor quinone is thermodynamically favorable. The quinone was attached to the naphthalimide via an N-methylethanolamine linker through a carbamate to the amine of the naphthalimide ring. This linker imparts three crucial properties on Q3NI: the linker is sufficiently short to allow for a high probability of electron transfer, the electron-withdrawing carbamate yields a favorable \( \Delta G_{PeT} \), and the presence of the tertiary amide provides enhanced environmental stability.\textsuperscript{23,25} As a result, the fluorescence of Q3NI in pH 7.4, 0.1 M PBS is effectively quenched in comparison to that of the free NI reporter, as noted by their spectra in Figure 1B and 1C and respective fluorescence quantum yields (\( \Phi \)) of 0.007 and 0.23 obtained using quinine sulfate as standard.\textsuperscript{26} The quantum yield for NI is superior or comparable to that of other dyes applied to cancer detection and localization, such as \( \Phi = 0.0028 \) for indocyanine green and \( \Phi = 0.21 \) for Cy5.5 dyes.\textsuperscript{13,27} The 33-fold fluorescence enhancement for NI versus Q3NI and very large Stokes shift of 116 nm (\( \lambda_{\text{max, abs}} = 374 \text{ nm, } \lambda_{\text{max, em}} = 490 \text{ nm} \)) bode well for use of Q3NI as a multifunctional turn-on probe for sensing and imaging applications that utilize reductive stimuli capable of initiating removal of the reduced quinone group.\textsuperscript{28–31}
Fluorescence Dequenching of Q₃NI is Achieved by Reduction-initiated Removal of Quinone

We then wished to determine if it is possible to produce the NI reporter from the Q₃NI probe by the expected cyclizative cleavage reaction of the hydroquinone via the gem-dialkyl effect that occurs subsequent to two-electron reduction of the quinone. Thus, the strong reducing agent sodium dithionite was added to aqueous solutions of Q₃NI. Under these conditions, it was found that NI is rapidly released as indicated by the increase in time-dependent fluorescence intensity (Figure 2) at 470 nm (λₑₓ = 370 nm). To provide proof positive that the increase in fluorescence for reduced Q₃NI results from cyclizative cleavage of the hydroquinone reduction product as the lactone, a second probe (Q₁NI) was synthesized such that the rate of lactone formation from its hydroquinone form is >10³ times slower than in the case of reduced Q₃NI, due to the lack of the two methyl groups on the geminal carbon. Dithionite reduction of the Q₁ group is known to be equally fast as the Q₃ group. As seen in Figure 2, reduced Q₃NI exhibits exceedingly rapid NI reporter production in comparison to reduced Q₁NI; at 37 min (the maximum recorded for Q₃NI), the signal for reduced Q₃NI is 20-fold higher than that for Q₁NI. Although it could be argued the signal for reduced Q₃NI is attributable to the absence of photo-induced electron transfer quenching of the reporter by the hydroquinone of Q₃NI, a significantly favorable Δ𝐺ᵣᵣₑₜ of −3.37 eV for the reductive quenching process of the NI reporter by the hydroquinone clearly supports its occurrence. That is, once the quinone is reduced to its hydroquinone (HQ₃NI, Figure 1A), quenching of reporter fluorescence occurs by reductive electron transfer (ReT), a common feature with naphthalimide dyes. Furthermore, we have isolated and identified the NI reporter from Q₃NI solutions treated with dithionite (Figure S-6). Thus, the rapid increase in fluorescence for reduced Q₃NI results from naphthalimide dequenching caused by reduction-initiated removal of the quinone propionic acid group by lactonization. Due to the unique quenching mechanism of the Q₃NI turn-on probe sensor, pronounced fluorescence signal enhancement upon revealing the NI reporter and its large Stokes shift, and the known resistance of the quinone propionic acid trigger group to reduction by other biological species, we investigated Q₃NI as a sensor probe of human NAD(P)H:quinone oxidoreductase isozyme 1 (hNQO1) activity in real-time biological applications.

Q₃NI is Activated by hNQO1 at a High Rate

We determined if Q₃NI is a substrate capable of activation by hNQO1 to yield the NI reporter at a significant rate. To do so, we obtained the apparent kinetic parameters from Michaelis-Menten kinetic treatment of the time-dependent NI reporter production, namely the Michaelis constant (𝐾ᵣₑ), maximum velocity (𝑉ₑₓ), catalytic constant (𝑘ₑₓ), and substrate specificity (𝑘ₑₓ/𝐾ₑₓ). The high rate of NI reporter production under in vitro conditions is readily apparent in the inset of Figure 3; after 5 min, a fluorescent signal has been attained that is 22% of the maximum achievable, yielding 2.2 × 10⁻⁷ M of released reporter. From the plot shown in Figure 3, we obtained 𝐾ₑₓ = 3.86 ± 0.79 μM, 𝑉ₑₓ = 0.037 ± 0.002 μmol min⁻¹ mg⁻¹ NQO1⁻¹, 𝑘ₑₓ = 0.019 ± 0.001 s⁻¹, and 𝑘ₑₓ/𝐾ₑₓ = 4.94 ± 0.33 × 10³ M⁻¹ s⁻¹. Due to the presence of the non-bulky ethanolamine linker and the need of only a single activation step to reveal reporter fluorescence, the kinetic constants are significantly

J Am Chem Soc. Author manuscript; available in PMC 2016 January 06.
higher than those of other NQO1 activatable fluorophores,\textsuperscript{31,34,35} thereby ensuring sufficient signal enhancement for fast detection of hNQO1 activity.

**Cancer Cells can be Rapidly Visualized and Differentiated Based on hNQO1 Activation of Q\textsubscript{3}NI**

Our interest in the potential use of the Q\textsubscript{3}NI probe in microfluidic-based cell sorting/isolation of circulating tumor cells\textsuperscript{36} and fluorescence-guided resection of tumors\textsuperscript{3} led us to evaluate if the Q\textsubscript{3}NI probe can be used to discriminate between cancer cells of different origins and hNQO1 content, with and without the aid of sophisticated instrumentation. The colorectal carcinoma cell line HT-29 and the non-small cell lung cancer (NSCLC) A549 cell line are known to possess significant hNQO1 activity, while the NSCLC H596 cell line has been reported to have undetectable hNQO1 activity.\textsuperscript{37,38} After a 10-min incubation period in a cell culture solution containing 2 × 10\textsuperscript{−5} M Q\textsubscript{3}NI, it was possible to differentiate between the various substrate-cultured cells (4.84 cm\textsuperscript{2}) using only a hand-held fluorescent lamp emitting at 365 nm and the un-aided eye (Figure 4). Both HT-29 (3.69 × 10\textsuperscript{6} total cells) and A549 (5.72 × 10\textsuperscript{6} total cells) appeared fluorescent blue, while H596 (3.96 × 10\textsuperscript{6} total cells) exhibited no apparent emission. The ability to visually determine the presence of hNQO1 in a small number of cells is due to the marked difference in fluorescence from the unquenched NI reporter (Φ = 0.23) and quenched Q\textsubscript{3}NI probe (Φ = 0.007) and the large Stokes shift of the NI reporter that results in fluorescence emission in the visible spectrum (400 nm to ~600 nm). These outcomes point to potential use of the Q\textsubscript{3}NI probe sensor in the real-time, visible (without the aid of imaging equipment) and accurate determination of tumor/healthy tissue borders so as to allow for surgical resection of tumors with small foci.

Flow cytometry assays (Figure 5) were used to assess the applicability of the Q\textsubscript{3}NI probe to rapidly detect and quantify tumor cells containing hNQO1. The probe was incubated in a suspension of HT-29, A549, H596, and H446 (a small cell lung carcinoma known to be devoid of hNQO1 activity\textsuperscript{37}) cells for either 10 or 60 min, and a flow cytometer was used to measure the fluorescence (λ\textsubscript{ex} = 405 nm, λ\textsubscript{em} = 457/60 nm) in 10,000 individual cells. In Figure 5 are shown the histograms for each cancer cell line. It is clear that a high-intensity, unimodal distribution of signals is obtained for Q\textsubscript{3}NI activation in each of the two hNQO1-positive cell lines (HT-29 and A549), while the negative cell lines H596 and H446 produced minimal fluorescence. It was also found that there was little change in the cell count or intensity of the histograms for a longer probe incubation time (60 min vs. 10 min, Figure S3), demonstrating the rapid and substantial activation of Q\textsubscript{3}NI in A549 and HT-29 cells. Importantly, the sustained low fluorescence observed with the H446 cells (Figure S3) points to the intracellular stability of Q\textsubscript{3}NI (lack of non-specific activation). Thus, it is indicated that Q\textsubscript{3}NI is a highly sensitive and selective probe capable of being used to rapidly discern different types of tumor cells in fluidic streams.

**Live and Fixed hNQO1-containing Cancer Cells can be Selectively Imaged via Q\textsubscript{3}NI Activation**

We desired to know if cancer cell types can be differentiated in conventional fluorescence microscopy images resulting from Q\textsubscript{3}NI activation by hNQO1, and if it is possible to obtain images that allow collection of information regarding the fate of the released NI reporter.
Furthermore, we wished to learn if the NI reporter can be successfully used in upconversion fluorescence (multi-photon) imaging of live cells. In agreement with flow cytometry data, wide-field imaging of fixed hNQO1-positive cells exposed to the Q₃NI probe for 10 min revealed significant probe uptake and activation that leads to intracellular NI fluorescence for the A549 and HT-29 cell lines; however, minimal signal was observed in the hNQO1-negative H596 cells (Figure S4). There was no indication of reporter in the nucleus, pointing to the lack of NQO1 there; this is in clear contrast to previous work using immunohistochemical staining of permeabilized, fixed cells. The average cytosolic signal was 9 times higher in A549 cells versus NQO1-negative H596 cells, while it was 23 times higher in HT-29 cells compared to the NQO1-negative H596 cells. After incubating live HT-29 cells for 20 min with Q₃NI followed by exposure to acidic organelle-specific Lysotracker Red in the media in the imaging dish, it was found that the majority of the NI signal originated from the cytosolic region. Not surprisingly, accumulation of the basic (secondary amine pKₐ ~11) NI occurred in acidic late endosomal and lysosomal vesicles (Figure S5), a beneficial outcome that leads to enhanced intracellular retention of NI. The higher signal-to-background value achieved for activation of Q₃NI to NI reporter (9- to 23-fold) in target versus non-target cells, relative to that of other exogenously introduced sensor probes for whole tumor analysis (2.5- to 5-fold), points to the potential of Q₃NI to provide highly selective tumor cell analyses with low limits of detection, even in the face of possible background fluorescence from hemoglobin and other species. In addition, our results indicate that dye quantum yield is affected little, and there is no apparent efflux of NI reporter from cells during paraformaldehyde fixing, as noted by sustained fluorescence in fixed samples stored for 10 months in the laboratory ambient. Collectively, there is great potential for use of our probe/reporter system for ex vivo quantitative analysis of excised tumor cells and long-term in vivo and in vitro imaging.

Multiphoton (MP) microscopy imaging of cells and tissues is more advantageous when compared to traditional fluorescence microscopy, because use of the characteristic long-wavelength photons offers higher fluorophore and cellular photostability that provides extended imaging duration, less background signal from out-of-focus excitation and scattering events, and deeper penetration depth. In addition, MP imaging is ideal for direct observation of targets in their physiological environment and ex vivo thick-specimen sampling where 2D and 3D maps can be generated. During incubation with complete growth medium containing 2.0 × 10⁻⁵ M Q₃NI, 2-photon microscopy revealed significant fluorescence signal from NI in living, hNQO1-positive HT-29 and A549 cells (Figure 6) and minimal signal in two living, hNQO1-negative cell lines, H596 and H446. The average fluorescence signal was determined to be 13-fold higher in A549 cells compared to H596 cells, and 3.66 × 10⁴-fold higher versus H446 cells. Similar results were obtained with the HT-29 cell line, with the cytosolic intensity being 15- and 4.51 × 10⁴-fold higher compared to H596 and H446 cells. As before, the signal appears somewhat heterogeneous throughout the cytosolic space of the HT-29 and A549 cells due to NI accumulation in acidic organelles. To ensure Q₃NI and NI had little effect on cell health, cells were incubated in a 2.0 × 10⁻⁵ M Q₃NI solution in complete growth medium for one hour and one day, and then cell viability was assessed with a trypan blue assay. After 1 h, cell viability for HT-29, A549, and H596 was 97.7%, 98.8%, and 100%, while it was 97.7%, 98.7%, and 98.4% after
24 h. Of particular importance is the real-time nature of the $Q_3$NI probe in imaging, as this system does not require the time-consuming wash steps characteristic of always-on reporters.$^{1,4}$

**CONCLUDING REMARKS**

In summary, we have presented the successful development and implementation of a quenched turn-on probe whose fluorescent reporter signal is selectively and quickly generated and maintained in human cancer cells upon activation by a cancer-associated-enzyme substrate that is subsequently removed from the probe to yield the free de-quenched reporter dye. Specifically, intracellular reduction of the quinone substrate by NAD(P)H:quinone oxidoreductase and successive self-removal of the reduced substrate from the reporter leads to elimination of the photo-induced electron-transfer quenching event, thereby yielding the naphthalimide reporter possessing a highly intense and Stokes-shifted emission. As a result, we have achieved rapid and highly selective/sensitive detection, differentiation, and enumeration of cancer cells in flowing streams and under traditional microscopy conditions without the use of recognition agents, an outcome that has in turn allowed for imaging of live cancer cells by multi-photon fluorescence microscopy. The latter outcome bodes well for in vivo and ex vivo thick-specimen imaging, where the efficacy of treatment protocols and the cellular impact of pharmaceutical targets can be evaluated for personalized oncology. Finally, control over the emission characteristics of the reporter dye$^{22}$ coupled to our ability to visibly see, by the un-aided eye, relatively small numbers of cancer cells, reveals the potential of this new class of probes for application to fluorescence-guided surgical resection of cancerous tissues.

**EXPERIMENTAL**

Full details regarding materials, synthesis of compounds, and their characterization are described in the Supporting Information.

**Cell Culture**

HT-29 (human colorectal adenocarcinoma), A549 (human non-small cell lung cancer, NSCLC), H596 (human NSCLC), and H446 (human small-cell lung cancer) were all purchased from American Type Cell Culture. HT-29 cells were cultured in McCoy’s 5A medium supplemented with 10% fetal bovine serum (FBS) and 100 IU/mL penicillin-streptomycin, A549 cells were cultured in F-12K medium with 10% FBS and 100 IU/mL penicillin-streptomycin, and H596/H446 were cultured in RPMI-1640 with 10% FBS and 100 IU/mL penicillin-streptomycin. Cells were incubated at 37 °C in a humidified incubator containing 5% wt/vol CO$_2$.

**Flow Cytometry**

To a 1-mL suspension of cells ($1 \times 10^6$) in complete growth medium was added $Q_3$NI from a stock dimethylsulfoxide (DMSO) solution to give a final $[Q_3$NI$] = 2 \times 10^{-5}$ M and [DMSO] $\sim$1%. After 10- or 60-min incubations at 37 °C, the cells were fixed with 30 mL of 4% paraformaldehyde in 0.1 M PBS for 1 h, followed by washing twice with 0.1 M PBS, and then resuspending in 1 mL PBS. Data acquisition was carried out on an iCyt Reflection
flow cytometer using 405-nm excitation and a 457/60 nm emission filter; logarithmic amplification was used. Winlist software (Verity Software House, Topsham, ME) was used to count 10,000 cells per sample; FlowJo software was used to construct histograms.

**Enzyme Kinetics**

All fluorescence measurements ($\lambda_{ex} = 390$ nm, $\lambda_{em} = 470$ nm) were obtained at room temperature, with solutions composed of pH 7.4, 0.1 M PBS/0.1 M KCl/0.007% BSA. A stock solution of $1 \times 10^{-4}$ M $\beta$-nicotinamide adenine dinucleotide, reduced disodium salt (NADH, Sigma-Aldrich), was made with the PBS buffer; this NADH solution was subsequently used to prepare all other solutions so as to have a final concentration of $1 \times 10^{-4}$ M $\beta$-NADH in each assay. Solutions consisting of $2 \times 10^{-6}$ to $6 \times 10^{-5}$ M $Q_3$NI were made using the NADH stock. A 1.33 $\mu$g/mL stock solution of recombinant human NQO1 (Sigma-Aldrich) was prepared using the same buffer as above so as to give $2.0 \times 10^{-5}$ g hNQO1 per assay. Each assay was performed in a quartz fluorescence cuvette containing 1.5 mL $Q_3$NI solution and initiated by the addition of 1.5 mL hNQO1 solution. Measurements were collected every 30 s for 5 min. Fluorescence units were converted to concentration by relating the signal increase to a fluorescence signal derived from a known concentration of NI. Plots of velocity versus $Q_3$NI concentration were used to obtain apparent $K_m$ and $V_{max}$ values from non-linear least squares analysis employing algorithms developed by Cleland for Michaelis-Menten kinetics.  

**Cell Viability**

Cells were cultured in 5 mL of complete growth medium in a sterile tube. To the medium was added $Q_3$NI (from a $1.8 \times 10^{-3}$ M stock solution) in DMSO, to give a $2.0 \times 10^{-5}$ M $Q_3$NI solution, and the cells were incubated at 37 °C, 5% CO$_2$ for 1 h or 24 h, after which 1 mL of the cell suspension was removed and then 0.1 mL trypan blue was added. Cells were immediately counted using a hemocytometer and microscope.

**Optical Differentiation**

HT-29, A549, and H596 cells were cultured overnight on 2.2 × 2.2 cm glass cover slips. Old growth medium was removed and replaced with a $2.0 \times 10^{-5}$ M $Q_3$NI solution in fresh growth medium. Cells were incubated at 37 °C with $Q_3$NI for 10 min and then rinsed with 0.1 M PBS. Cover slips of each cell line were immediately placed upside down on glass slides and visualized with a Kodak digital camera in conjunction with a Mineralight Model UVGL-25 lamp (365 nm, 0.16 amps, 60 Hz).

**Confocal Colocalization**

Confocal fluorescence images were acquired with a Leica TCS SP5 tandem scanning multiphoton laser scanning microscope using a 40x oil immersion objective lens (1.25 NA). Imaging of Lysotracker Red- and $Q_3$NI-exposed cells was accomplished using a sequential scanning method with $\lambda_{ex} = 405$ nm at 10% output and collecting emission between 417 and 467 nm ($Q_3$NI) or $\lambda_{ex} = 561$ nm at 10% output, and the emitted light was collected between 574 and 621 nm (Lysotracker Red). Differential interference contrast (DIC) images were obtained using a PMT detector and 633-nm light at 3% output as an illumination source. All
images were collected at 37 °C using the Leica TCS SP5 in resonant scanning mode (16 KHz) at a zoom setting of 3.6. Images were line averaged 64 times. Cells were cultured overnight in black 35 × 10 mm, 22-mm well, glass-bottom dishes (Chemglass Life Sciences). Prior to imaging, the medium was removed and replaced with medium (containing no phenol red) and maintained at 37 °C. A concentrated solution of Q3NI in DMSO was added directly to the dish to give a concentration of 2.0 × 10^{-5} M, with [DMSO] ≤ 1%. Cells were incubated with Q3NI for 20 min. Five min prior to imaging, Lysotracker Red-DND 99 in DMSO was added to give a concentration of 1 × 10^{-7} M.

In vitro 2-Photon Imaging

Two-photon confocal fluorescence images were acquired as above using a MaiTai two-photon laser tuned to 750 nm (3% laser power, modelocked Ti:sapphire laser; Tsunami Spectra Physics), and emission was collected using a short-pass 680-nm filter. DIC images were collected as above. Cells were imaged, with no washing or medium removal steps, after a 10-min incubation with Q3NI. Image analysis was performed in ImageJ.

Images of cells were captured with a digital camera upon irradiation at λ_ex = 365 nm with a hand-held lamp. Scale bar represents 1 cm.
Flow cytometry assays of Q₃NI activation by hNQO1-positive (A549 and HT-29) and hNQO1-negative (H596 and H446) cancer cells. Assays were performed by counting 10,000 cells that had been exposed to $2.0 \times 10^{-5}$ M Q₃NI probe for 10 min; $\lambda_{\text{ex}} = 405$ nm, $\lambda_{\text{em}} = 457/60$ nm.
Figure 6.
Two-photon confocal microscopy imaging of living HT-29 (A,E), A549 (B,F), H596 (C,G), and H446 (D,H) cells in the presence of $2.0 \times 10^{-5} \text{ M Q}_3\text{NI}$ probe. Fluorescence images of each cell line are on the top row with their respective differential interference contrast (DIC) image on the bottom row. Images were acquired at $\lambda_{ex} = 750$ nm (3% laser power) without any washing steps between Q$_3$NI probe addition and imaging. Scale bars represent $2.5 \times 10^{-5}$ m.
