Inchoate CD8\(^+\) T Cell Responses in Neonatal Mice Permit Influenza-Induced Persistent Pulmonary Dysfunction\(^1\)

Dahui You,\(^*\),\(^\dagger\) Michael Ripple,\(\dagger\) Shrilatha Balakrishna,\(^*\) Dana Troxclair,\(\dagger\) Dane Sandquist,\(\dagger\) Liren Ding,\(2^*\) Terry A. Ahlert,\(^*\) and Stephania A. Cormier\(^3^*\)

Influenza infection remains a significant cause of pulmonary morbidity and mortality worldwide, with the highest hospitalization and mortality rates occurring in infants and elder adults. The mechanisms inducing this considerable morbidity and mortality are largely unknown. To address this question, we established a neonatal mouse model of influenza infection to test the hypothesis that the immaturity of the neonatal immune system is responsible for the severe pulmonary disease observed in infants. Seven-day-old mice were infected with influenza A virus (H1N1) and allowed to mature. As adults, these mice showed enhanced airway hyperreactivity, chronic pulmonary inflammation, and diffuse emphysematous-type lesions in the lungs. The adaptive immune responses of the neonates were much weaker than those of adults. This insufficiency appeared to be in both magnitude and functionality and was most apparent in the CD8\(^+\) T cell population. To determine the role of neonatal CD8\(^+\) T cells in disease outcome, adult, naive CD8\(^+\) T cells were adoptively transferred into neonates before infection. Neonatal mice receiving the adult CD8\(^+\) T cells had significantly lower pulmonary viral titers and greatly improved pulmonary function as adults (airway resistance similar to SHAM). Additional adoptive transfer studies using adult CD8\(^+\) T cells from IFN-\(\gamma\)-deficient mice demonstrated the importance of IFN-\(\gamma\) from CD8\(^+\) T cells in controlling the infection and in determining disease outcome. Our data indicate that neonates are more vulnerable to severe infections due to immaturity of their immune system and emphasize the importance of vaccination in infants. The Journal of Immunology, 2008, 181: 3486–3494.

Copyright © 2008 by The American Association of Immunologists, Inc. 0022-1767/08/$2.00 flu/weekly/weeklyarchives2006–2007/06 – 07summary.htm). Interestingly, the highest incidence of illness occurs in preschool and school age children, with 20–30% of children in this age group being diagnosed with influenza infections each year (3–6). Infected infants younger than 6 mo of age have higher hospitalization and mortality rates than do older children (7, 8). Complications of influenza infections in infants typically include lower respiratory tract involvement and, although these infections occur less frequently than respiratory syncytial virus (RSV) infections in infants, they are also a significant cause of wheeze (9). Epidemiological data demonstrate that infection of infants with influenza can lead to chronic pulmonary distress and furthermore that the effects of influenza in this population are underestimated and may be responsible for previously unexplained chronic pulmonary dysfunction (10).

To understand how influenza induces pulmonary illness, various animal models have been used, including ferrets, rats, chickens, and mice (11). While neutralizing Abs to influenza are important for protection from viral infection, CD8\(^+\) T cells have been shown to play a pivotal role in viral clearance and recovery from the illness in adult mice. CD8\(^+\) T cell-deficient mice exhibit delayed viral clearance and significantly higher mortality when challenged with a sublethal dose of influenza (12). Additionally, in B cell-deficient mice, adoptive transfer of CD8\(^+\) T cells promotes more rapid clearance of the virus and recovery from illness (13, 14).

Despite the global burden of influenza infection in infants and children, very few studies have examined the pathogenesis of infection in an infant model. The infant and neonatal immune systems are immature and this immaturity contributes to the pathogenesis of various lower respiratory tract infections, including influenza, RSV, and others. Lower respiratory tract viral infections in infants are often associated with acute and persistent pulmonary dysfunction, which is characterized by increased airway resistance and hyperresponsiveness (15–17). Previously, we and other groups
have described a neonatal mouse model (i.e., 7 days of age at initial infection) of RSV infection (18–20). In this model, the age of primary infection determined the immunological nature (Th1 or Th2) of the secondary infection. Th2 immune responses dominated upon secondary infection, if the primary infection occurred at 1 wk or less of age; while Th1 responses dominated if the mice were primarily infected as adults (8 wk old) (18). Interestingly, a single infection with RSV in neonatal mice induced long-term pulmonary dysfunction (20), which was exacerbated upon secondary infection with RSV (19). The RSV neonatal model demonstrated that the age at which the initial infection occurred is critical in determining the subsequent host immune response to the pathogen; furthermore, it suggested that if the infection occurs too early, the immature immune response contributes to pathogenesis instead of protection.

A recent study in human infants suggests that a failure to develop a cytotoxic T lymphocyte response is responsible for the high rate of infant morbidity and mortality caused by respiratory viruses (21). The article demonstrated that in both fatal infant influenza and RSV infection, CD4+ and CD8+ T cells were present in the lung at very low frequency. Additionally, granzyme-producing cells (either cytotoxic CD8+ T cells or NK cells) were not observed in the lungs of infants with fatal influenza virus infection and correlated with massive viral replication and apoptosis of inflammatory cells.

To understand the relationships among the type of respiratory virus, the pulmonary immune response and the long-term pulmonary pathophysiology after infection in infancy, we established a neonatal (7 days of age) mouse model of influenza A virus infection. In this model, neonatal infection induced long-term pulmonary inflammation and airway injury and dysfunction accompanied with a weak CD8+ T cell response (lower number and lower IFN-γ production in CD8+ T cells). To examine if the weak CD8+ T cell response played a role in the pathogenesis of influenza infection in neonates, we adoptively transferred adult CD8+ T cells into neonatal mice before infection with influenza. Our data demonstrate that the insufficient production of IFN-γ by neonatal CD8+ T cell may be responsible for the long-term pulmonary inflammation and lung injury in influenza-infected neonatal mice.

Materials and Methods

Mice

BALB/c mice were purchased as breeders from Harlan Sprague Dawley. IFN-γ knockout mice (C.129S7(B6)-Ifngtm1Ts/J) were purchased from The Jackson Laboratory. Mice were maintained under specific pathogen-free conditions within the vivarium at Louisiana State University Health Sciences Center (New Orleans, LA). Sentinel mice within each colony were monitored and were negative for specific known mouse pathogens. Breeders were time-mated and 7-day-old pups (neonates) were used for experiments. All animal protocols were prepared in accordance with the Guide for the Care and Use of Laboratory Animals (22) and approved by the Institutional Animal Care and Use Committee at Louisiana State University Health Sciences Center.

Viral infection and viral titer determination

Human influenza A/PR/8/34 (H1N1) was purchased as a sucrose gradient-purified virus from Advanced Biotechnologies. The virus preparation was determined to be free of bacteria, yeast, and fungi. Viral titer was measured in whole lung homogenates at different time points (Fig. 1) using the TCID₅₀ method of Spearman and Kärber (23, 24). Mardin-Darby canine kidney cells were seeded on a 96-well plate and then inoculated with a series of 10-fold dilutions of lung homogenates. Cells were then incubated at 37°C and 5% CO₂ for 4 days; wells showing cytopathic effects were counted and TCID₅₀ were calculated.

Experimental design

Seven-day-old pups were infected intranasally with 10 TCID₅₀/g body weight of influenza (FLU) in 10 μl of Dulbecco’s PBS or sham infected with 10 μl Dulbecco’s PBS (SHAM). Mouse pups were then allowed to mature and various assays were performed at the indicated time points as outlined in Fig. 1A. For adoptive transfer studies, CD8+ T cells from naive wild-type adults (FLU/CD8A), wild-type neonates (FLU/CD8N), or IFN-γ knockout mice (FLU/CD8AKO) were administrated i.p. to 6-day-old pups; at 7 days of age, these pups were then infected with influenza (Fig. 1B). Four groups of mice were included as controls: vehicle-treated pups (SHAM), influenza-infected pups (FLU), vehicle-treated adult mice (ASHAM), and influenza-infected adult mice (AFLU). A range of assays were performed at indicated time points as shown in Fig. 1B.

Pulmonary function test

Pulmonary function, specifically the respiratory mechanics, were measured using an invasive method as previously described (20). Briefly, anesthetized mice were intubated and mechanically ventilated by a computer controlled piston ventilator (flexiVent, Scireq). Mice were then challenged by...
an aerosolized bronchoconstrictor methacholine (Sigma-Aldrich) at increasing doses (methacholine (MeCh): 0, 25, and 50 mg/ml). At each dose, lung resistance and compliance were calculated using the single compartment model.

**Lung histopathology**

At different time points, lungs were perfused, inflated by gentle infusion of HistoChoice tissue fixative (Amresco) to tidal volume (6 ml/kg), and isolated (Fig. 1). The fixed lungs were then dehydrated, embedded in paraffin, and sectioned at 4 µm. Each lung section was stained with either H&E or periodic acid-Schiff (PAS). Specific histopathological diagnoses were performed by unbiased pathologists (D.T. and D.S.). Initial observations of the influenza-infected lungs suggested emphysematous-type lesions. Morphometric analyses of the lung sections were used to quantify these changes in lung architecture, including airspace enlargement (i.e., mean linear intercept, or Lm), and destruction of alveolar walls (i.e., destructive, or DI). Lm was quantified using the National Institutes of Health Image program (http://rsb.info.nih.gov/nih-image). The number of alveolar wall intersections was counted on 12 nonoverlapping lung fields and was expressed as micrometers using a protocol adapted from Thurlbeck (25). To measure DI, a grid with 42 equidistant points (100 lung fields and was expressed as micrometers using a protocol adapted from Thurlbeck (25). To measure DI, a grid with 42 equidistant points (100

**Bronchoalveolar lavage fluid (BALF) cellularity and cytokine measurement**

BALF was isolated in 1 ml of PBS containing 2% heat-inactivated FBS at the indicated time points (Fig. 1). The cells were then centrifuged onto slides and stained using a Hema-3 staining kit (Fisher Scientific). Two unbiased reviewers counted a total of 300 cells per slide and recorded the differential cell counts based on the morphology and staining of the cells. Cytokine levels were measured from 50 µl of cell-free BALF using a high-throughput multiplex cytokine Mouse System (x-Plex Mouse; Bio-Rad) according to the manufacturer’s instructions. Each sample was analyzed in triplicate on the Bio-Plex 200 system (Bio-Rad). A broad sensitivity range of standards ranging from 1.21 to 37,312 pg/ml (depending on the analyte) was used to quantitate a dynamic range of cytokine concentrations. The concentrations of analytes in these assays were quantified using a standard curve, and a five-parameter logistic regression was performed using an interpolation equation that was then used to predict the concentration of the unknown samples. The following cytokines were assayed: IL-2, IL-4, IL-5, IL-6, IL-12p40, IL-12p70, IL-13, IL-17, IFN-γ, and TNF-α. The data presented herein excluded any number below the range of sensitivity for the particular analyte.

**Assessment of pulmonary T cell populations**

A single-cell suspension of lung cells was prepared using a standardized protocol (27). Briefly, lungs were perfused, excised, cut into small pieces, and incubated at 37°C for 1 h in RPMI 1640 media supplemented by 2% heat-inactivated FBS, 1 mg/ml collagenase I (Intronig), and 150 µg/ml DNase I (Sigma-Aldrich). After incubation, single cells were obtained by mashing the lung pieces through a 40-µm cell strainer (BD Biosciences). RBC were lysed using 1× RBC lysis buffer (eBioscience), and the remaining cells were stained with fixable (i.e., CD3, CD4, and CD8) and permeabilized (fixation and permeabilization buffer; eBioscience), and stained with the following Abs purchased from Immunomics) from influenza A nucleoprotein without PMA/ionomycin stimulation. Cell staining was determined with an LSRII (BD Biosciences) flow cytometer after gating on the lymphocyte population as determined by forward and side scatter properties. Flow data were analyzed and plotted using FlowJo software (version 7.2.2 for Windows, Tree Star).

**Adaptive transfer of CD8+ T cells**

The protocol is modified from the method developed by Wells et al. (28). In brief, single-cell suspensions were prepared from the spleens of young adult (4 wk of age), adult IFN-γ knockout mice (4 wk old), or neonatal (7-day-old) mice using a standardized protocol as above. CD8+ T cells were then isolated using a negative selection strategy according to the manufacturer’s directions (mouse CD8+ T cell enrichment kit, StemCell Technologies). Neonatal, adult, or IFN-γ knockout adult CD8+ T cells (4× 10^6 in 25 µl of PBS) were then injected i.p. into 6-day-old pups (CD8N, CD8A, CD8AKO, respectively).

**Statistical analysis**

All data were plotted as means ± SEM and analyzed using GraphPad Prism software (version 5.0.0). Two-way ANOVA and Bonferroni post-tests were used to test for differences between the groups for the pulmonary function, BALF cellularity, cytokine assays, and T cell populations. Student’s t test was used to analyze the differences in lung histopathology parameters (Lm and DI). Differences were considered statistically significant if p < 0.05.

**Results**

**Neonatal influenza infection resulted in acute pulmonary inflammation**

BALB/c pups were infected at 7 days of age with 10 TCID50 of influenza A virus/g body weight (FLU); controls received sterile Dulbecco’s PBS (SHAM). Mice infected with this sublethal dose (>90% survival) of influenza developed mild-to-moderate illness, which was characterized by ruffled fur and significant reductions in weight gain compared with SHAM. By 18 days postinfection (dpi), mice infected with influenza weighed 12% less than SHAM animals (p < 0.05). Infectious influenza virus was detected in whole lung homogenates in neonatal mice as early as 2 dpi (10^4.46 ± 0.03) TCID50/g lung tissue) and peaked at 5 dpi (10^6.93 ± 0.23 TCID50/g lung tissue). No infectious viruses were detected in neonatal or adult mice after 7 dpi.

To measure pulmonary inflammation, BALF cellularity, BALF cytokine levels, and lung histopathology were monitored throughout the course of the infection (Figs. 2 and 3). All results from SHAM mice at different time points (5 h, 1, 2, 4, and 10 days postinfection) were similar and showed no difference (data not shown), and therefore only data from 10 dpi were presented as a representative. Mice infected with influenza recruited significantly more inflammatory cells to the lung as observed in both the lung and the BALF. Monocytes/alveolar macrophages (AMs) were shown to be recruited to the bronchoalveolar space as early as 5 h postinfection (hpi, Fig. 2A), and significantly more cells compared with SHAM were observed at 4 and 10 dpi with the peak at 10 dpi (44.09 ± 6.83 vs 13.19 ± 1.92 × 10^6). Neutrophils in the BALF showed the same trend. They peaked at 2 dpi (3.20 ± 1.11 vs 0.12 ± 0.02 × 10^6) and remained elevated at 10 dpi compared with the SHAM group (2.58 ± 0.75 vs 0.08 ± 0.03 × 10^6). A significant increase in lymphocytes was observed at 10 dpi (8.47 ± 3.79 vs 0.01 ± 0.01 × 10^6). Total BALF cell numbers were 5-fold higher in the FLU group compared with the SHAM group at 10 dpi (6.30 ± 10.70 vs 13.30 ± 1.92 × 10^6, p < 0.05).

Cytokines in the BALF peaked at various times during the infection (Fig. 2B). Although a total of 10 cytokines (IL-2, IL-4, IL-5, IL-6, IL-12p40, IL-12p70, IL-13, IL-17, IFN-γ, and TNF-α) were measured, only six (IL-5, IL-6, IL-12p40, IL-13, IFN-γ, and TNF-α) were detectable at the time points tested. Of these cytokines detected (with the exception of IFN-γ), all were elevated at 5 hpi. TNF-α was one of the earliest cytokines detected and was present in the highest concentration at 5 hpi (72.0 ± 2.55 pg/ml). It remained significantly elevated at 2 dpi (65.0 ± 28.3 pg/ml) and was undetectable by 10 dpi. IL-12p40 gradually increased from 5 hpi to 10 dpi, where it became significantly elevated over SHAM
were determined for the following cytokines: IL-2, IL-4, IL-5, IL-6, IL-10, IL-12, IL-13, IL-17, and IFN-γ.

**Histopathologic examination**

Histopathologic examination of lungs from neonatally infected mice revealed marked pulmonary inflammation that was observed in the perivascular, peribronchial, and alveolar spaces of the lung (right panel). Lungs were isolated, fixed, and stained with H&E and PAS at 10 dpi. The inflammatory infiltrates consisted of lymphocytes and occasional plasma cells. Additionally, extensive mucus production was observed in the goblet cells of the infected lungs, along with proliferation of peribronchial glands within the hilum in the influenza-infected mice (right panel). SHAM mice showed no mucus staining. Scale bar = 50 μm. Each image is representative of four different animals.

**Neonatal influenza infection led to long-term pulmonary dysfunction and injury**

To investigate the long-term effects of neonatal influenza infection, a group of 7-day-old pups were infected with the virus and allowed to mature to 116 days of age (109 dpi, Fig. 1A). As with the acute studies, BALF cellularity, BALF cytokine levels, and lung histopathology were recorded at 109 dpi.

Significantly more total cells were present in the BALF of previously infected mice compared with SHAM animals at 109 dpi (6.05 ± 1.89 vs 2.59 ± 0.70 × 10^7, p < 0.05). As shown in Fig. 4, there were significantly more monocytes/AMs (51.02 ± 8.79 × 10^5) present in the BALF of infected animals compared with SHAM mice (25.08 ± 5.17 × 10^5). Neutrophils (14.42 ± 6.47 × 10^5) and lymphocytes (6.20 ± 3.24 × 10^5) were higher than in SHAM mice (1.08 ± 0.53 and 0.25 ± 0.07 × 10^5, respectively), although not significantly different (p = 0.074). Eosinophils were not observed in the BALF of either FLU or SHAM mice. None of the cytokines assayed in the BALF at 109 dpi was significantly different than that of controls (data not shown).

The persistent change in BALF cellularity at 109 dpi suggested that there might also be unresolved pulmonary inflammation in the lungs of the adult mice initially infected with influenza as neonates. Indeed, lung histopathologic examination (Fig. 5A, right panel) confirmed mild-to-moderate peribronchial chronic inflammation consisting mostly of lymphocytes. Furthermore, moderate mucus production was still present in the goblet cells of infected lungs (Fig. 5B, right panel). Diffuse emphysematous changes with focal areas of minimal thickening within the alveolar walls were also observed in the infected lungs. Emphysematous lesions were

![figure2](image2.png)

**FIGURE 2.** BALF cellularity and cytokine levels in neonatal mice after infection. A, BALF was isolated and the cellularity determined at 5 hpi and at 2, 4, and 10 dpi. Absolute cell numbers were plotted vs time postinfection (n = 4–5/group). Mac indicates macrophages; Neu, neutrophils; Lym, lymphocytes; Eos, eosinophils. B, Cytokine levels in the BALF supernatant were determined for the following cytokines: IL-2, IL-4, IL-5, IL-6, IL-12p40, IL-12p70, IL-13, IL-17, IFN-γ, and TNF-α. Only detected cytokines are displayed on the graph (n = 3–5/group). Data are expressed as means ± SEM: *, p < 0.05; **, p < 0.01; and ***, p < 0.001 compared with SHAM.

![figure3](image3.png)

**FIGURE 3.** Lung histopathology following neonatal influenza infection. Lungs were isolated, fixed, and stained with H&E and PAS at 10 dpi. A, H&E staining showed marked inflammation in the perivascular, peribronchial, and alveolar spaces of the infected lung (right panel). Diffuse emphysematous changes were also observed in the infected lungs along with slight thickening of the alveolar walls. SHAM mice showed no inflammation or emphysematous changes (left panel). Scale bar = 100 μm. B, PAS staining demonstrated widespread mucus production and proliferation of peribronchial glands within the hilum in the influenza-infected mice (right panel). SHAM mice showed no mucus staining. Scale bar = 50 μm. Each image is representative of four different animals.

![figure4](image4.png)

**FIGURE 4.** BALF cellularity in adult mice infected with influenza as neonates. BALF was isolated at 109 dpi and leukocyte populations were determined. Data are expressed as means ± SEM (n = 4–5/group): *, p < 0.05. Mac indicates macrophages; Neu, neutrophils; Lym, lymphocytes; Eos, eosinophils.
Reduced IFN-γ+ T cells are observed in the neonate in response to influenza infection

To dissect the possible mechanism(s) responsible for the observed long-term pulmonary dysfunction, pulmonary T cell responses were measured using intracellular cytokine staining in influenza infected neonates (FLU) and adults (AFLU; 4 wk old) at 7 dpi (Fig. 7A). Approximately 2-fold more CD8+ T cells (9.7 ± 1.1 vs 5.2 ± 1.3 × 105) and slightly more CD4+ T cells (1.67 ± 0.18 vs 1.41 ± 0.48 × 105) were present in the adult lungs compared with the neonatal lungs (Fig. 7, A and B, left panel). Additionally, neonates infected with influenza appeared to mount a weak IFN-γ response to the virus compared with that of adults (Fig. 7, A and B, middle panel). Adult mice infected with influenza (AFLU) were able to recruit almost 6-fold more CD8+IFN-γ+ T cells (12.3 ± 1.92 vs 2.76 ± 1.92% of CD8+ T cells) and 2-fold more CD4+IFN-γ+ T cells (4.04 ± 0.67 vs 1.92 ± 0.34% of CD4+ T cells) to the lung as compared with the neonates. CD4+IFN-γ− T cells in neonates were statistically different from SHAM levels (0.61 ± 0.07% of CD4+ T cells). No difference was observed in the number of CD4+IL-4− T cells recruited to the lungs of mice infected with influenza as neonates or adults (data not shown). To examine the specificity of the CD8+ T cells recruited to the lung, we stained lung lymphocytes with H-2Kd tetramers containing the immunodominant epitope from the influenza nucleoprotein (Fig. 7B, right panel). Influenza infection of adult mice resulted in the recruitment of about 2-fold more CD8+ T cells that bound the influenza tetramer compared with infection of neonatal mice (2.29 ± 0.16% vs 1.24 ± 0.04%).

Reversal of long-term pulmonary dysfunction after adoptive transfer of adult CD8+ T cells but not neonatal CD8+ T cells

To determine whether the persistent pulmonary inflammation, altered lung structure, and long-term lung dysfunction were due to the functional immaturity of host lymphocytes or other factors (e.g., IFN-γ), CD8+ T cells were purified from the spleen of naive neonatal, adult, or adult IFN-γ-deficient mice and adoptively transferred to 6-day-old pups (Fig. 1B). One day later, these mice were then infected with 10 TCID50/g body weight of influenza (FLU/CD8N, FLU/CD8A, or FLU/CD8AKO, respectively). In addition, neonatal and adult mice were simply infected with influenza (FLU and AFLU, respectively). Pulmonary function testing, BALF cellularity, and lung histopathology were performed at 30 dpi.

Both FLU/CD8N and FLU/CD8A groups showed an improvement in pulmonary function, as evidenced by lower airway hyperreactivity compared with control FLU mice (2.89 ± 0.94 and 1.45 ± 0.46 vs 5.17 ± 1.35 cm H2O·s/ml at 50 mg/ml MeCh, Fig. 8A). Since noninfected control mice, either adults or neonates at time of sham infection, exhibited almost identical responses (data...
not shown), only the noninfected control mice that were sham infected as neonates (SHAM) are presented. Compared with the FLU/CD8N group, the FLU/CD8A group showed significantly lower pulmonary resistance at 50 mg/ml MeCh (1.00 ± 0.17 cm H₂O · s/ml). Moreover, the resistance of FLU/CD8A mice was comparable to that of SHAM mice (1.25 ± 0.21 cm H₂O · s/ml). In contrast, FLU/CD8N mice had higher resistance compared with SHAM mice, although pulmonary resistance was lower than that of the FLU mice (2.05 ± 0.39 vs 4.12 ± 0.93 cm H₂O · s/ml).

Interestingly, AFLU mice showed medium airway hyperreactivity: lower than mice infected as neonates (FLU) and higher than FLU/CD8A mice. Finally, adoptive transfer of adult CD8⁺ T cells deficient in IFN-γ prior to infection (FLU/CD8AKO) was unable to reverse the effects on pulmonary dysfunction observed in mice infected with influenza as neonates (resistance at 50 mg/ml MeCh of 5.80 ± 1.83 vs 5.17 ± 1.35 H₂O · s/ml).

Lung histopathology was also greatly improved in the FLU/CD8A mice as compared with FLU, FLU/CD8N, and FLU/CD8AKO. Scale bar = 100 µm.
CD8AKO mice. These improvements included reduced pulmonary inflammation (Fig. 8C) and mucus production (data not shown) in the infected lungs at 30 dpi. Adoptive transfer of adult CD8\(^{+}\) T cells was not able to completely reverse pulmonary inflammation at 30 dpi, since small foci of inflammatory cells were still observed in the peribronchial and perivascular areas of the lung (Fig. 8C). Although the lungs from AFLU mice exhibited similar levels of inflammation as observed in the FLU, FLU/CD8N, and FLU/ CD8AKO mice (Fig. 8C), there were no emphysematous-type lesions and little to no mucus (data not shown).

BALF cellularity showed the same trend (Fig. 8B). FLU/CD8A had fewer monocytes/AMs (18.07 \(\pm\) 1.32 vs 39.24 \(\pm\) 9.35 \(\times\) 10\(^4\)) and lymphocytes (0.37 \(\pm\) 0.24 vs 2.82 \(\pm\) 1.41) in BALF compared with FLU controls, although a significant amount of neutrophils were still present (10.54 \(\pm\) 3.23 vs 12.40 \(\pm\) 3.61 \(\times\) 10\(^4\)). Conversely, transfer of neonatal CD8\(^{+}\) T cells (FLU/CD8N) or adult IFN-\(\gamma\)-deficient CD8\(^{+}\) T cells (FLU/CD8AKO) prior to infection did not reduce cellular infiltrates in BALF, as there were no differences observed between these two groups and FLU controls. Interestingly, adult mice infected with influenza (AFLU) had significantly elevated numbers of neutrophils and lymphocytes, but not monocytes/AMs, in their BALF compared with SHAM mice.

The ability of neonatal mice to resolve infection following adoptive transfer of the adult or neonatal CD8\(^{+}\) T cells was then analyzed. Viral titers were determined at 4 and 30 dpi from lung homogenates. The FLU/CD8A group showed a significantly lower viral load compared with FLU mice (10\(^{2.40}\) \(\pm\) 0.040 vs 10\(^{6.42}\) \(\pm\) 0.53 TCID\(_{50}\)/g lung tissue). AFLU mice also had lower viral titers than FLU mice (10\(^{3.57}\) \(\pm\) 0.18 vs 10\(^{7.42}\) \(\pm\) 0.63 TCID\(_{50}\)/g lung tissue). Additionally, FLU/CD8A mice had a significantly lower viral load than did AFLU mice at 4 dpi (10\(^{2.30}\) \(\pm\) 0.040 vs 10\(^{3.57}\) \(\pm\) 0.18 TCID\(_{50}\)/g lung tissue). Significant differences were observed between FLU/CD8N and FLU or FLU/CD8AKO and FLU mice, although titers in both groups were slightly lower than in the FLU group (data not shown). At 30 dpi, virus was no longer detectable in any group.

Discussion

In the present study, we described a neonatal mouse model of influenza A infection. In this model, BALB/c mice were infected with influenza virus at 7 days of age and allowed to mature. The mice developed acute, severe pulmonary inflammation, which remained unresolved 4 mo later and long after influenza virus was no longer detectable. This correlated with significant increases in pulmonary resistance in response to increasing doses of methacholine (i.e., airway hyperreactivity) and decreases in compliance at 4 mo. Histopathologic analysis of the lungs from adult mice infected as neonates revealed emphysematous-type lesions characterized by airspace enlargement and destruction of alveolar walls. Adoptive transfer of adult CD8\(^{+}\) T cell into the pups before infection with influenza reversed the effects of neonatal influenza infection as evidenced by enhanced pulmonary function (returning airway resistance to SHAM levels) and reduced pulmonary inflammation and reduced viral load compared with pups receiving neonatal CD8\(^{+}\) T cells. Adoptive transfer of adult CD8\(^{+}\) T cells deficient in IFN-\(\gamma\) indicated that IFN-\(\gamma\) was critical in determining disease outcome.

The inflammatory cells in the BALF during the acute phase (5 hpi to 10 dpi) and chronic phase (109 dpi) included monocytes/AMs, lymphocytes, and neutrophils. Interestingly, although there were more cells in the BALF at 10 dpi than at 109 dpi (\(\sim\)50% more), the composition of the BALF was not significantly altered (i.e., both were comprised of \(\sim\)80% of monocytes/AMs and 20% of lymphocytes and neutrophils), suggesting the continued presence or secretion of chemokines responsible for neutrophil and lymphocyte recruitment even in the absence of detectable infectious virus or viral Ag. At 109 dpi, we were unable to detect differences in cytokines between mice infected as neonates and SHAM controls; however, the role of other cytokines or inflammatory mediators (e.g., leukotrienes) cannot be excluded.

In addition to the chronic inflammation and airway hyperreactivity to MeCh, histopathologic analysis of the lungs from adult mice originally infected as neonates revealed emphysematous-type lesions within the lung architecture. Intriguingly, there were no differences in baseline resistance between this group and SHAM controls at 109 dpi despite significant differences in lung architecture and inflammatory state. The reason(s) for this are unclear, but may represent masking due to the persistent inflammation or a limitation of the model chosen (i.e., single compartment) to measure respiratory mechanics.

In general, the immune system of a neonate is quite different from that of an adult, in that the innate and adaptive immune responses are immature (29, 30). Naive, neonatal T cells are also functionally distinct from adult T cells (31), and effector, neonatal T cells are less able to lyse Ag-bearing cells or produce cytokines (32). Although neonatal T cells are able to mount comparable proliferative responses to mitogens (33), they have intrinsically lower levels of CD3/TCR, adhesion molecules, and costimulatory molecules (34). Data from our studies indicate that recruitment of T cells is different in the infected neonates vs the adult, and although both T cell populations are induced in the neonate, CD8\(^{+}\) T cell numbers are doubled in the adults. This suggested that cell number alone may have been responsible for the pathophysiological impact of neonatal influenza infection. Although adoptive transfer of neonatal CD8\(^{+}\) T cells before infection did help to control the infection (i.e., reduced viral load and improved pulmonary function compared with neonates infected with influenza), it was not as effective as adoptive transfer of adult CD8\(^{+}\) T cells (i.e., further reduction in viral load and pulmonary function equivalent to that of SHAM). These data suggest that neonatal CD8\(^{+}\) T cells are functionally impaired compared with adult CD8\(^{+}\) T cells.

In addition to the lower magnitude of the T cell response in the neonates, the numbers of IFN-\(\gamma\)-deficient CD8\(^{+}\) T cells was significantly lower than those of their adult counterparts after influenza infection. Previous studies have showed that IFN-\(\gamma\) plays an important role in recovery from influenza infection by helping to clear the virus (35, 36) and that adoptive transfer of Tc1 cells (IFN-\(\gamma\)-deficient CTLs) promotes clearance of the influenza virus, while transfer of Tc2 cells (IFN-\(\gamma\)-deficient CTLs) does not affect viral clearance (37). Our data confirmed that IFN-\(\gamma\) produced by CD8\(^{+}\) T cells was important to effectively clear influenza from the neonatal lung, since mice receiving IFN-\(\gamma\)-deficient adult CD8\(^{+}\) T cells showed higher viral loads than mice receiving wild-type adult CD8\(^{+}\) T cells. Moreover, adoptive transfer of IFN-\(\gamma\)-deficient CD8\(^{+}\) T cells totally abolished the benefits observed upon administration of adult CD8\(^{+}\) T cells, as demonstrated by increased airway hyperreactivity, BALF cellularity, and lung histopathology (similar to neonatal infection controls). Collectively, our data further demonstrate the importance of IFN-\(\gamma\) in the resolution of infection and inflammation initiated upon infection of neonatal mice.

Viral load and immune function are inescapably linked. Also, it is readily apparent that CD8\(^{+}\) T cells do not directly affect disease outcome and that they alter the course of pathogenesis by acting against virus-infected cells (i.e., decreasing viral load) through production of IFN-\(\gamma\). This contention is strengthened by our observation that introduction of poorly functional neonatal CD8 T cells does not ameliorate disease or act against virus-infected cells, thereby permitting a higher viral load in the host. Mice receiving...
wild-type adult CD8+ T cells exhibited lower viral loads, improved pulmonary function, a reduction in total BALF cellularity, and a reduction in pulmonary inflammation compared with mice infected as adults.

Influenza and another common respiratory virus, RSV, infect the same human population (infants) but elicit different pulmonary diseases. It has been reported that Th2 (IL-4+/Th cells) responses dominate in neonatal immunity, while Th1 (IFN-γ+/Th cells) responses dominate in adults (38–42). However, studies from our laboratory and those of other groups clearly demonstrate that the immune response initiated by neonates is more complex (20). A previous study showed that RSV-infected neonatal mice mount a Th2-biased response when rechallenged as adults with RSV (18). Although a mixture of Th1 and Th2 cells is elicited in lungs during reinfection, there were significantly more (4-fold) Th2 cells in lungs compared with mice primarily infected as adults (18). Data from our laboratory showed that even at primary infection, neonatal RSV infection mounts a Th2-skewed response (20) compared with influenza infection (data presented herein). In fact, both infections mount a mixed Th1/Th2 response. Following influenza infection, ~5-fold more Th1 cells than Th2 cells were recruited to the lungs, while RSV infection recruited similar numbers of Th1 and Th2 cells. These data suggest that the immune response initiated in neonates is not predestined toward a Th2 response, as previously implied, and appears to depend on the Ag encountered. Besides the differences in responses of helper T cells to RSV and influenza, both viruses induce a weak CD8+ T cell response similar in magnitude and function. Finally, during neonatal RSV infections, although airway remodeling is present (i.e., increased basement membrane thickness, smooth muscle hypertrophy, subepithelial fibrosis), there is relatively no tissue destruction (20). In contrast, neonates infected with influenza exhibited a tremendous amount of tissue destruction, which may be the principal determinant of the severity of airway symptoms. Taken together, there is similarity and disparity in the immune responses induced by RSV and influenza, and the immune and cytopathic differences may explain the specific pulmonary diseases elicited by these two viruses.

In summary, our data demonstrate that infection of newborn mice with influenza has long-term consequences for the host, inducing diffuse emphysematous changes in the lung and marked pulmonary inflammation. These alterations were persistent and associated with increased airway resistance and reduced compliance. The adaptive T cell response was markedly reduced in the neonates, with the most striking difference being observed among the CD8+ T cell population. Our adoptive transfer data suggest that the immaturity of this cell population is an important factor in determining disease outcome in the context of the pulmonary microenvironment. These data, along with recent data suggesting that one lung infection has the potential to modify immunity for extended periods of time (43), emphasize the importance of delaying the time of initial influenza infection, and therefore the importance of vaccination in infants and young children. Future studies to elucidate the molecular mechanisms responsible for the persistent inflammatory and structural alterations observed with neonatal influenza infection should identify important therapeutic targets capable of controlling long-term complications due to viral bronchiolitis in infancy. Our observations (i.e., that CD8+ T cell responses in neonates are functionally different from those of adults) have significant implications for human infants beyond just influenza infection, including infant responses to nosocomial infections and even responses to vaccination.
