Abstract Oxygenic photosynthesis efficiency at increasing solar flux is limited by light-induced damage (photoinhibition) of Photosystem II (PSII), primarily targeting the D1 reaction center subunit. Some cyanobacteria contain two natural isoforms of D1 that function better under low light (D1:1) or high light (D1:2). Herein, rates and yields of photoassembly of the Mn_4CaO_5 water-oxidizing complex (WOC) from the free inorganic cofactors (Mn^{2+} , Ca^{2+} , water, electron acceptor) and apo-WOC-PSII are shown to differ significantly: D1:1 apo-WOC-PSII exhibits a 2.3-fold faster rate-limiting step of photoassembly and up to seven-fold faster rate to the first light-stable Mn^{3+} intermediate, IM_1^* , but with a much higher rate of photoinhibition than D1:2. Conversely, D1:2 apo-WOC-PSII assembles slower but has up to seven-fold higher yield, achieved by a higher quantum yield of charge separation and slower photoinhibition rate. These

results confirm and extend previous observations of the two holoenzymes: D1:2-PSII has a greater quantum yield of primary charge separation, faster $[\text{P}_{680}^+ \text{Q}_\text{A}^-]$ charge recombination and less photoinhibition that results in a slower rate and higher yield of photoassembly of its apo-WOC-PSII complex. In contrast, D1:1-PSII has a lower quantum yield of primary charge separation, a slower $[\text{P}_{680}^+ \text{Q}_\text{A}^-]$ charge recombination rate, and faster photoinhibition that together result in higher rate but lower yield of photoassembly at higher light intensities. Cyanobacterial PSII reaction centers that contain the high- and low-light D1 isoforms can tailor performance to optimize photosynthesis at varying light conditions, with similar consequences on their photoassembly kinetics and yield. These different efficiencies of photoassembly versus photoinhibition impose differential costs for biosynthesis as a function of light intensity.

Introduction

The membrane-embedded Photosystem II (PSII) reaction center acts as a water-plastoquinone oxidoreductase in the light reactions of oxygenic photosynthesis (McEvoy and Brudvig 2006; Muh and Zouni 2011; Vinyard et al. 2013a). The active site for water oxidation (known as the water-oxidizing complex (WOC)) is a Mn_4CaO_5 hetero-cubane structure that is stabilized by various amino acid residues mainly from the D1 reaction center subunit (Umena et al. 2011). The WOC is assembled from free Mn^{2+} , Ca^{2+} , HCO_3^- , water, and a terminal electron acceptor in the apo-WOC-PSII complex through a process termed

Fig. 1 Top steps involved in removal of cofactors and photoassembly of PSII. Bottom sequence of kinetic intermediates during photoassembly

photoassembly (also known as photoactivation, Fig. 1) (Tamura and Cheniae 1987; Dasgupta et al. 2008; Chen et al. 1995). Photoassembly can be experimentally probed by detecting oxygen (the terminal product of the fully assembled WOC) using short flashes of light at varying flash frequencies. This technique has enabled determination of the stoichiometry of the metal ions (Ananyev and Dismukes 1996; Zaltsman et al. 1997) and the average oxidation state of the manganese ions (number of flashes needed to produce O₂) (Zaltsman et al. 1997; Kolling et al. 2012). In spinach and cyanobacteria, the kinetic sequence and chemical mechanism of photoassembly have been elucidated as follows (Fig. 1, reviewed in (Burnap 2004; Dasgupta et al. 2008)): Apo-WOC-PSII plus inorganic cofactors (IM₀) form the first light-induced Mn³⁺ intermediate (IM₁) upon one-electron photooxidation of a Mn²⁺ and release of a proton; this step occurs with a quantum yield of only 0.25–0.75 % in vitro (Baranov et al. 2004). Next, a slow (rate-determining) dark rearrangement step occurs in which Ca²⁺ binds within the ligand field of the high affinity Mn³⁺, forming intermediate IM₁*. IM₂ is next formed following one-electron photo-oxidation of a second Mn²⁺, and is rapidly converted to a functional WOC when exposed to additional light and the necessary cofactors. In spinach, the rate of formation of IM₁ is approximately ten-fold faster than the subsequent dark step that forms IM₁* (Ananyev et al. 1999; Zaltsman et al. 1997). Non-functional photoassembly intermediates form reversibly with the above productive pathway, leading to lower yields of active PSII-WOC, thus indicating careful coordination of cofactor availability and photon utilization is essential in vivo.

Little is known about how variations in PSII subunit content affect WOC photoassembly. Several groups have reported significant variations in PSII-WOC activity (O₂ evolution) as a function of natural variations in the cyanobacterial reaction center D1 subunit (coded for by the *psbA* gene) (Vinyard et al. 2013b; Sugiura and Boussac 2014; Mulo et al. 2012). For example, in the cyanobacterium *Synechococcus elongatus* PCC 7942, two isoforms, D1:1 and D1:2, differ by 25 out of 360 amino acids (Golden et al. 1986) and are differentially expressed based on

environmental conditions (Schaefer and Golden 1989a, b). D1:1 is expressed at low light and contains a Gln at position 130 that hydrogen bonds to the primary electron acceptor, pheophytin (Umena et al. 2011). D1:1 has more efficient WOC cycling at very low light intensities due to slower charge recombination reactions (Vinyard et al. 2013b). D1:2, which contains a Glu at position 130, is expressed at high light intensity, has faster charge recombination, and is significantly less sensitive to photoinhibition (Campbell et al. 1998; Clarke et al. 1993; Kulkarni and Golden 1994; Ogami et al. 2012; Sander et al. 2010; Tichy et al. 2003). By expressing D1:1 during normal growth conditions (low or moderate light intensities) and D1:2 during high light intensities, *Synechococcus* 7942 can maximize photosynthetic function in diverse light environments (Clarke et al. 1993; Vinyard et al. 2013b). In addition to D1:1 and D1:2, other D1 isoforms are present in various cyanobacteria including D1_m (expressed under normal growth conditions in *Synechocystis* sp. PCC 6803) and D1' (expressed under low oxygen conditions) (reviewed in Mulo et al. 2009; Sugiura and Boussac 2014).

We previously introduced the approach of expressing D1:1 or D1:2 from *Synechococcus* 7942 in a transgenic *psbA*-deficient strain of the green alga *Chlamydomonas reinhardtii* (Gimpel and Mayfield 2013; Vinyard et al. 2013b). In our previous studies, the choice of a *Chlamydomonas* background eliminated interference from phycobiliproteins and Photosystem I-associated chlorophylls in fluorescence studies. We found that the phenotypes exhibited by D1:1- or D1:2-PSII in *Synechococcus* 7942 were faithfully reproduced in the green algal system (Vinyard et al. 2013b). Seven additional D1 point mutants were constructed in these backgrounds that exhibited systematic variations between these native isoforms, confirming the robustness of these variations in vivo (Vinyard et al. 2014). With these strains in hand, we hypothesized that D1 isoforms may also affect the rate and/or yield of WOC photoassembly. Using flash oximetry experiments, we show that the presence of D1:1 leads to a faster rate of photoassembled WOC, while the presence of D1:2 leads to a higher final yield of photoassembled WOC at higher

intensities. Implications for photosynthetic efficiency are discussed.

Materials and methods

Chlamydomonas reinhardtii strains in which the native *psbA* copies have been interrupted and D1:1 and D1:2 isoforms from *Synechococcus elongatus* PCC 7942 heterologously expressed were available from a previous study (Gimpel and Mayfield 2013; Vinyard et al. 2013b, 2014). These strains were generated from wild-type CC-125 (137c, mt⁺), which was used as a control. The three strains used in this study (D1:1, D1:2, and CC-125) have D1 proteins with identical C-terminal domains (after Ala344) to avoid differences in post-translational processing. Photoautotrophic cultures were maintained in HS medium (Sueoka 1960) with 5 mM HCO₃[−] and thylakoid membrane fragments were isolated, as previously described (Vinyard et al. 2013b). Briefly, cells were lysed using a BeadBeater (Bartlesville, OK) with zirconia beads and thylakoid membranes were isolated by centrifugation. Thylakoid membranes were resuspended in Buffer B (20 mM MES, pH 6.0, 15 mM NaCl, 5 mM MgCl₂, and 5 mM EDTA) and 25 % Triton X-100 was slowly added to a final Triton X-100/Chl ratio of 20:1 and a Chl concentration of 2.0 mg mL^{−1}. After 25 min. of slow stirring, thylakoid membrane fragments were washed three times in Buffer B, and resuspended at ~2 mg Chl mL^{−1} in 25 % glycerol, 300 mM sucrose, 50 mM MES, pH 6.0, and 35 mM NaCl. Aliquots were flash frozen in liquid N₂ and stored at 77 K.

Apo-WOC-PSII was generated by first incubating *C. reinhardtii* whole cells in a reducing agent, 1 mM hydroxylamine (NH₂OH), in darkness for 1 min before cell lysis (Tamura and Cheniae 1987; Cheniae and Martin 1971; Hwang and Burnap 2005). After thylakoid membrane fragments were isolated, NH₂OH-treated samples were sequentially incubated with 200 mM MgCl₂ in alkaline CHES buffer (20 mM, pH 9.4) for 1 min at room temperature to release Mn²⁺ and Ca²⁺ and the extrinsic PSII subunits. Bound PsbO slows photoassembly by hindering Mn²⁺ accessibility to PSII (Miyao and Murata 1984), as well as hindering complete Mn²⁺ release from the WOC during Mn depletion (Kuwabara et al. 1985). Two volumes of 50 mM MES and 1 mM EDTA were then added to quench the alkaline treatment and chelate released Mn²⁺ (modified from Hunziker et al. 1987). This optimized protocol eliminates O₂ evolution below detection limit, while allowing high yields of photoassembly.

Chlorophyll was extracted in methanol and quantified using extinction coefficients from Porra (Porra et al. 1989). The concentration of PSII reaction centers was determined

by electron paramagnetic resonance (EPR) detection of tyrosine-D radical (Y_D). Samples were illuminated with a red LED ($\lambda_{\text{max}} = 623 \text{ nm}$, $500 \mu\text{E m}^{-2} \text{ s}^{-1}$) for 30 s at 0 °C, dark adapted for 10 min at 0 °C, and then quench cooled in liquid nitrogen in darkness. The double integral of the Y_D signal was quantified against a standard curve of Fremy's salt (Babcock et al. 1983). Manganese content in each sample was also assessed via EPR. 100 μL of each sample at $1.5 \text{ mg Chl mL}^{-1}$ was digested with 400 μL concentrated nitric acid (trace metal analysis grade, Sigma Aldrich, St. Louis, MO) and incubated for 1 h at room temperature. Samples were spun down at $15,000\times g$ and 200 μL of supernatant was loaded into quartz EPR tubes. The peak-to-trough height of the first (low-field) feature of the six-line Mn²⁺ signal was quantified to compare relative Mn²⁺ content.

Flash O₂ yield was measured using a homemade membrane-covered O₂ electrode described previously (Ananyev and Dismukes 1996). The electrode was equipped with a pulsed LED light source ($\lambda_{\text{max}} = 660 \text{ nm}$, $85 \mu\text{E m}^{-2} \text{ s}^{-2}$) that was used to generate flashes of variable duration (5–60 ms) and flash frequency (0.1–1 Hz, 10–1 s dark time between flashes).

Each flash O₂ run was performed with 0.5 μM PSII as thylakoid membrane fragments in a total volume of 13 μL . All experiments included 50 mM MES, pH 6.0, 300 mM sucrose, 35 mM NaCl, and 2 mM K₃Fe(CN)₆. For photoassembly experiments, 10 mM CaCl₂, 0.1 mM MnCl₂, and 10 mM NaHCO₃ were added (complete photoassembly buffer).

As previously described (Baranov et al. 2004), experimental kinetics of reconstitution of O₂ evolution by photoassembly exhibit lag and growth phases that were fit to a biexponential model, Eq. 1:

$$Y(t) = Y_{\text{O}_2} + A_1 e^{-\lambda_1 t} - A_2 e^{-\lambda_2 t}, \quad (1)$$

where $Y(t)$ is the ensemble population of all O₂ evolving centers at time t , Y_{O_2} is the maximum (steady-state) population at the end of photoassembly, and A_1 and A_2 represent the relative amplitudes of the lag (λ_1) and growth (λ_2) phases of $Y(t)$, respectively. This kinetic equation represents a three-step microscopic process in which a fast reversible light-induced step (k_1/k_{-1}) is followed by a much slower (rate-limiting) dark step (k_2), and all subsequent steps leading to an active center are fast and unresolved. At all conditions of the photoassembly experiments conducted herein, $k_1 \gg k_2$, and the analytical solution to Eq. (1) simplifies to $\lambda_1 = (k_1 + k_{-1})$ and $\lambda_2 = k_2 k_1 / (k_1 + k_{-1})$ (Baranov et al. 2004).

Data represent the ensemble averages of three independent experiments. The averaged data were fit to Eq. 1, and error is reported as uncertainty in fits.

Results

We elected to work with isolated thylakoid membranes instead of detergent-solubilized PSII particles to ensure results would describe native PSII centers and by avoiding possible differential detergent solubilization kinetics (unanticipated). Isolated thylakoid membrane samples (holo-WOC-PSII) exhibited steady-state O_2 evolution rate at saturating light intensity of $267 \mu\text{mol } O_2 (\text{mg Chl})^{-1} \text{ h}^{-1}$ for CC-125, $161 \mu\text{mol } O_2 (\text{mg Chl})^{-1} \text{ h}^{-1}$ for D1:1-PSII, and $188 \mu\text{mol } O_2 (\text{mg Chl})^{-1} \text{ h}^{-1}$ for D1:2-PSII as measured in the standard buffer (40 mM MES, pH 6.0, 200 mM sucrose, 10 mM NaCl, 10 mM CaCl_2 , 10 mM MgCl_2 , 0.1 mM DCBQ, and 2 mM $\text{K}_3\text{Fe}(\text{CN})_6$). The Y_D radical EPR signal in holo-WOC-PSII samples was measured and quantified against a standard curve of Fremy's salt to determine absolute PSII concentrations (Fig. 2). The ratio of Chl to Y_D (Chl/PSII) was determined to be 356 for CC-125, 487 for D1:1, and 546 for D1:2, in agreement with our previous study (Vinyard et al. 2013b).

An optimal flash duration that produces adequate O_2 signal and low photoinhibition was determined for intact thylakoid membranes and found to be 30 ms (Fig. 3). This duration was used for all subsequent experiments. It is essentially the same duration flash as found for native spinach thylakoid membranes (Ananyev and Dismukes 1996). Shorter flashes produce insufficient time for Mn^{2+} binding and photooxidation, as seen by the lower yield of O_2 and the greater number of flashes required to reach the steady state (see 5 vs. 15 and 30 ms). Longer flash durations are less effective in restoring O_2 evolution on the first flash, and all subsequent flashes inhibit further by a bimolecular process that increases with the Mn^{2+}

concentration. This Mn-dependent inhibition by long pulses arises from photooxidation of additional Mn^{2+} at non-functional site(s) that block native assembly (Ananyev et al. 2001; Chen et al. 1995). This bimolecular inhibition process is known to be reduced by Ca^{2+} , and on this basis has been assigned to the binding and photooxidation of Mn^{2+} at the Ca^{2+} effector site to form a misfolded protein or misassembled cluster (Ananyev et al. 2001; Chen et al. 1995).

Confirmation that a previously developed method for cofactor extraction (NH_2OH incubation followed by alkaline salt washing and final EDTA washing of thylakoid membrane fragments) also works well for *C. reinhardtii* thylakoid fragments was performed in two ways: EPR analysis of Mn^{2+} content, and O_2 evolution of the depleted

Fig. 3 Holo-WOC-PSII from CC-125 was used to optimize the LED flash duration. Flash rate from 0.33 Hz. $0.5 \mu\text{M}$ PSII was suspended in 50 mM MES, pH 6.0, 300 mM sucrose, 35 mM NaCl, and 2 mM $\text{K}_3\text{Fe}(\text{CN})_6$

Fig. 2 *Left* EPR signals from Fremy's salt standards were integrated twice and used to generate a quantitative standard curve for spin concentration. *Right* the EPR spectra of Y_D in thylakoid membrane fragments were used to determine the PSII concentrations for

normalization of photoassembly data. All samples were analyzed at 9.45 GHz frequency, 0.1 mW power, 2 G modulation amplitude at 10 ± 1 K for 32 scans

Fig. 4 **a–c** EPR analysis of the Mn²⁺ signal intensity reveals that ~60 % of the Mn²⁺ was removed from apo-WOC-PSII samples. Samples were analyzed at 9.36 GHz frequency, 0.25 mW power (**a** and **b**) or 0.5 mW power (**c**), and 15 G modulation amplitude at

12 ± 1 K. **d–f** Flash O₂ yields (Y_{O₂}) of apo-WOC-PSII and holo-WOC-PSII samples. All samples contained 0.5 μM PSII in 50 mM MES, pH 6.0, 300 mM sucrose, 35 mM NaCl, and 2 mM K₃Fe(CN)₆. 10 mM CaCl₂ or 0.1 mM MnCl₂ was added as indicated

thylakoid membrane fragments with incomplete cofactor addition. EPR analysis of the residual Mn²⁺ content of apo membrane fragments is similar: apo/holo ratios of 0.367 in CC-125, 0.392 in D1:1, and 0.420 in D1:2 (Fig. 4). The ~40 % residual population of Mn²⁺ in the apo-WOC-PSII thylakoids is consistent with earlier papers by Cheniae (1980), Blankenship and Sauer (1974), and with our prior results using spinach thylakoids membranes. The flash O₂ yields of apo-WOC-PSII membranes were below the detection limit in blank buffer (50 mM MES, pH 6.0, 300 mM sucrose, 35 mM NaCl, 2 mM K₃Fe(CN)₆) and when either 0.1 mM Mn²⁺ or 10 mM Ca²⁺ was added

(Fig. 4). These controls demonstrate that the WOC is not functional in apo-samples, and that the residual Mn content in thylakoids is not available to reconstitute O₂ evolution capacity, neither with added Mn²⁺ nor added Ca²⁺ alone.

The kinetics of photoassembly exhibit an observable lag phase prior to a mono-exponential growth phase to maximum yield and, and in some cases, light-dependent decay of the maximum yield occurs (negative slope following maximum) (Fig. 5). The latter decay is due to photoinhibition (Ananyev et al. 2001; Baranov et al. 2004). The photoinhibition contribution was typically small or zero during the photoassembly period and could be removed by

linear extrapolation of the negative slope following the peak in photoassembly to zero time (dashed line in Fig. 5). This correction for photoinhibition was always larger in CC-125-PSII and D1:1-PSII than in D1:2-PSII samples.

Fig. 5 Apo-WOC-PSII samples for CC-125 (a), D1:1 (b), and D1:2 (c) were compared at the flash frequencies which gives the highest observed photoassembly yields (0.2 and 0.33 s^{-1} , respectively). $0.5\text{ }\mu\text{M}$ of holo-WOC-PSII (black lines) or apo-WOC-PSII (gray traces) was suspended in complete photoassembly buffer. PSII was quantified using Y_D content (Fig. 2). The maximal flash oxygen yield was corrected for photoinhibition by linear extrapolation of the post maximum decay (dashed lines)

The flash frequency was varied from 0.1 Hz to 1 Hz in steps to simulate the transition from low to high light intensities, and the steady-state O_2 yields were determined. As illustrated in Fig. 5, after approximately 400 flashes, a steady-state yield is reached and CC-125-PSII and D1:2-PSII produce significantly more O_2 than D1:1-PSII at the chosen flash rate. Comparison of the flash rate dependence of Y_{O_2} , given in Fig. 6a, shows that D1:2-PSII photoassembles a higher yield of centers when using faster

Fig. 6 D1:1 apo-WOC-PSII (closed symbols) or D1:2 apo-WOC-PSII (open symbols) was photoassembled using 30 ms flashes applied at 0.1 – 1 Hz (resulting in 10 – 1 s dark time between flashes) in complete photoassembly buffer. **a** steady-state photoassembly yield, **b** rate constant λ_2 representing the rate-limiting assembly step, and **c** k_1k_2 ($=\lambda_1\lambda_2$) representing the product of forward rate constants from IM_0 to IM_1^*

flash frequencies (≥ 0.33 Hz), while D1:1-PSII exhibits its maximal O_2 yield at slower flash frequencies, from 0.2 Hz and below. The maximum ratio of photoassembled O_2 yield (Y_{O_2}) between D1:2 and D1:1 is 7:1 at 0.5 Hz and 1:2 at 0.1 Hz flash rate, respectively (Fig. 6a), indicating a strong dependence on the average light intensity. For comparison, at high light intensity, the D1:2-PSII holoenzyme has been previously shown to have a 16–40% higher steady-state turnover frequency for O_2 production than D1:1-PSII holoenzyme in vitro (Sugiura et al. 2008; Vinyard et al. 2013b) and a 50–70 % higher primary charge separation efficiency (equal to the primary photochemical quantum yield, Φ) in vivo (Vinyard et al. 2014). These differences in relative photochemical rate for the holoenzymes versus the photoassembly reaction follow the same pattern but quantitatively differ, suggesting other contributions. This should be expected considering the complexity of the photoassembly process which is known to produce misassembled centers (depending upon the cofactor concentrations) that do not contribute to O_2 recovery initially, but may be reversibly reactivated (Ananyev et al. 2001; Chen et al. 1995; Dasgupta et al. 2008).

Figure 5 compares the steady-state flash O_2 yield of photoassembled apo-WOC-PSII centers to that for the intact holo-WOC-PSII, prior to cofactor extraction, at the indicated flash rates. This comparison shows that the final O_2 flash yields of the photoassembled centers are approximately 76 % for CC-125, 60 % for D1:2, and 40 % for D1:1. These yields are quite high considering that the absence of the extrinsic PsbO subunit alone lowers the flash O_2 yield by approximately 30 % in spinach (Hunziker et al. 1987; Tamura and Chéniaie 1987; Zaltsman et al. 1997). All three extrinsic subunits of PSII are missing from apo-WOC-PSII samples.

The kinetics of photoassembly exhibit both lag and growth phases in agreement with previous results from spinach thylakoids and grana membranes (Ananyev et al. 2001; Baranov et al. 2004). As before, the time-dependent yield, $Y(t)$, was fitted to the biexponential expression shown as Eq. 1. This model provides excellent numerical fits with low residuals (R^2 in the range 0.923–0.998; Table 1). The “assembly phase” macroscopic rate constant, λ_2 , obtained from these fits is rate-limiting for photoassembly and is plotted as a function of flash rate in Fig. 6b. For both D1:1-PSII and D1:2-PSII, the fastest photoassembly rate occurs at 1 Hz flash rate (the fastest rate examined) and decreases with decreasing flash frequencies. This trend is as expected for a light intensity-dependent process of low quantum yield, and is consistent with earlier behavior seen for spinach (Baranov et al. 2004; Zaltsman et al. 1997). D1:1 assembles at comparable or slightly faster rate than D1:2 at all flash rates examined below 0.5 Hz (Fig. 6b). As the

flash rate increases to 1 Hz, D1:1 photoassembles at 2.3-fold faster rate compared to D1:2.

The value of λ_1 , the “lag phase” macroscopic rate constant, is approximately 7–9-fold faster than λ_2 , while its amplitude (A_1) contributes only a small fraction (11.5% average) of the total signal (A_1 is 8- to 13-fold smaller than A_2 over the range of flash frequencies studied; Table 1). This outcome is by choice as we deliberately used high concentrations of Mn^{2+} and Ca^{2+} relative to the apo-WOC-PSII concentration to ensure high photoassembly yields and low photoinhibition rates (Baranov et al. 2004). High Mn^{2+} and Ca^{2+} concentrations directly contribute to shortening the lag phase in spinach thylakoids and grana membranes, making it difficult to measure with precision (Baranov et al. 2004). Under these conditions, the precision of measuring λ_1 is insufficient to allow a statistically significant difference between D1:1 and D1:2 to be determined.

Discussion

The data show that the two natural D1 isoforms offer clear advantages at different light intensities for assembling active PSII-WOC centers capable of supporting photosynthesis through water oxidation. This process provides the primary energy equivalents for cellular growth in the form of reducing equivalents (electrons) and proton gradient. D1:1-PSII assembles more WOC centers at low light flux, while D1:2-PSII assembles more WOC centers at high light flux. D1:1 assembles at rates equal to or faster than D1:2 at all measured light intensities, while becoming significantly faster at higher light intensities (1 Hz) where the rate of photooxidation to form Mn^{3+} in IM_1 (given by microscopic rate constant k_1 , Fig. 1) dominates over the dark charge recombination reaction (microscopic rate constant k_{-1}). However, at these high light intensities, D1:1 suffers from faster photoinhibition than does D1:2, significantly limiting is overall yield of activated centers.

The kinetic parameters λ_1 and λ_2 in Eq. 1 can be used to obtain the microscopic rate constants k_1 and k_2 in the reaction model (Fig. 1) as described above. Here we see that the two isoforms are kinetically indistinguishable in terms of their forward product fluxes at flash rates of 0.5 Hz and slower. From these expressions, we obtain the product of the forward rate constants, $k_1k_2 = \lambda_1\lambda_2$, which is plotted as a function of flash rate in Fig. 6c. This product may also be thought of as the inverse of the product of transit times required to go from IM_0 to IM_1^* without any recombination. Hence, the only explanation for the greater final yield of photoassembled D1:1-PSII-WOC centers at these slower flash rates is because of a slower charge recombination rate (k_{-1}). This interpretation of the

Data from three replicates were ensemble averaged and then fit to the function $Y_{O_2} = y_0 + A_1 e^{-\lambda_1 x} - A_2 e^{-\lambda_2 x}$

photoassembly kinetics fits precisely with the experimentally measured slower charge recombination rate of the D1:1-PSII holoenzyme which is dominated by $[Q_A^- P_{680}^+]$ recombination (Vinyard et al. 2013b; Sugiura and Boussac 2014; Vinyard et al. 2014). Figure 6c also shows that above 0.5 Hz flash rate, D1:1 has a faster forward flux from IM_0 to IM_1^* than does D1:2 (seven-fold larger at 1 Hz flash rate), but produces fewer active centers than does D1:2 (Fig. 6a). The only way this can happen is if the high light flux causes greater photoinhibition in D1:1. Again, this agrees with the experimentally determined faster photoinhibition rate of D1:1-PSII holoenzyme (Vinyard et al. 2013b; Sugiura and Boussac 2014; Vinyard et al. 2014).

Previous studies in isolated PSII reaction centers from *Thermosynechococcus elongatus* BP-1 containing either D1:1 or D1:2 have revealed that the midpoint potentials of both Pheo/Pheo⁻ (Kato et al. 2009; Sugiura et al. 2010) and Q_A/Q_A^- (Kato et al. 2012; Ogami et al. 2012) are significantly more negative in D1:1-PSII. These differences have been used to explain the higher quantum yield of primary charge separation in D1:2-PSII (larger free energy gap between P_{680}^*/P_{680}^+ and Pheo/Pheo⁻) and the slower recombination events in D1:1-PSII (dominated by $[Q_A^- P_{680}^+]$ recombination) (Vinyard et al. 2013b; Sugiura and Boussac 2014; Vinyard et al. 2014). These traits are likely responsible for the functional advantage in photoassembly kinetics for cells containing D1:1 in low-light conditions, and cells containing D1:2 in high light conditions (Vinyard et al. 2013b).

While PSII centers containing D1:2 have higher photoassembly yields at high light intensities (Fig. 6a), the rate of photoassembly is significantly slower than centers containing D1:1 (Fig. 6b, c). We note that maximal photosynthetic efficiency would be achieved with both a high yield and a fast rate. However, in order to maintain efficient

photo-protection in the holoenzyme, the D1:2 isoform pays the price of slower WOC photoassembly.

In this study, we have extended the knowledge of the relative advantages of D1:1 versus D1:2 to include photoassembly yields and kinetics. The higher photoassembly yield observed for D1:2-PSII correlates with its higher quantum yield of charge separation which provides greater protection against photoinhibition. By contrast, in D1:1-PSII, WOC assembly is faster at low light intensities due to slower $[Q_A^- P_{680}^+]$ recombination kinetics. We postulate that a faster rate of photoassembly may provide an evolutionary advantage for cyanobacteria expressing the D1:1 isoform in low-light environments. It is significant to note that cyanobacteria, that can express these two isoforms of D1 in response to environmental cues, must pay appreciably different energy costs to assemble the same number of functional PSII centers at high light intensity where the substantially faster photoinhibition rate of D1:1 greatly limits the yield of functional PSII centers. These data affirm that Nature has developed a mechanism for maintaining water oxidation capability under varying light regimens and thus another mechanism for controlling the efficiency of photosynthesis.

Acknowledgments This work was supported by grants from the National Science Foundation-Chemistry of Life Processes, CHE1213772 (to GCD), and the U.S. Department of Energy, Consortium for Algal Biofuels Commercialization, Grant DE-EE0003373 (to SPM). JSS was supported by the Waksman Institute of Microbiology and the Aresty Research Center for Undergraduates at Rutgers University. DJV was supported by the Department of Defense Army Research Office through a National Defense Science and Engineering Graduate (NDSEG - 32CFR168a), and a National Science Foundation Graduate Research Fellowship, DGE-0937373. JG was supported by the Comisión Nacional de Investigación Científica y Tecnológica de Chile (CONICYT). We thank Clyde Cady for assistance with EPR measurements.
