## **ACKNOWLEDGEMENTS**

I would like to thank all of my advisors as well as friends and family, without which this degree would not have been possible. I also want to thank my daughter for keeping me company during the final writing process. Special consideration to the McCord Chair in an effort to fund many key analyses essential to this project. I would also like to show appreciation for the Coastal Institute Fellowship and Moffet Scholarships for financial academic support throughout this process.

## **ABSTRACT**

Given the significant degree to which the modern Mississippi River and its tributaries have been altered through dams, levees, and diversions, it is important to understand how sediment is transported from source to sink. The objective of this dissertation is to explore how the modern Mississippi River transports sediment from its tributaries to its delta using three independent proxies. Provenance indicators have traditionally been an effective way with which to characterize sediment transport in large river systems. First, detrital U-Pb zircon dating is used to investigate modern flux and possible anthropogenic influences on coarse-grained sediment within the modern Mississippi River. Overall, results indicate that samples taken from the modern river show regional flux and possible repercussions of the Red River diversion into the Atchafalaya basin. Secondly, apatite geochemistry is used to determine its viability as an independent provenance indicator when used on detrital populations with large sample sizes. In the end, it is concluded that when quantitative analysis is used to enhance variability between samples, these results compare closely with detrital zircon U-Pb spectra. Finally, Nd and Sr samples are evaluated from a core taken within the modern Mississippi River delta. From this data, it is concluded that  $\epsilon\text{Nd}$  values from the Mississippi River remain relatively stable until modern human alterations shift the geochemical signature in the top of the core.

## **CHAPTER 1. INTRODUCTION**

### **1.1 Overview**

Rivers are the cornerstones of many geologic sediment transport systems, with drainages that range from small scales to those that cover continents. They erode and weather terranes and transport sediment from source to sink. They carry sediment within suspended or bedload through the river until it is eventually delivered into the marine basin. This transport process can be stalled as sediment is temporarily stored within the floodplain, delta, and sometimes within the river channel itself. Recently, the natural order of this geologic process has been altered due to intensive human engineering projects which have fundamentally changed the dynamics of sediment transport through rivers (Rogers, 2005). In general, the alterations humans have made to the fluvial landscapes in which they live have resulted in dire consequences for floodplain nourishment, delta progradation, beach nourishment, and land subsidence in coastal landscapes (M. D. Blum & Roberts, 2009; Boesch et al., 1994)

The Mississippi River and its tributaries drain 2/3 of the eastern continental United States. For decades, this major fluvial thoroughfare has experienced concentrated artificial engineering, which has profoundly changed the way in which the river transports sediment from its headwaters to the coast. The intensified construction of dams, locks, river control structures, and levees has not only curtailed sediment flux, it has cut the Mississippi River off from its floodplain and deltas. In the case of the Red River, human diversion projects have completely cut off sediment supply from one of the Mississippi's main tributaries to the main trunk and delta.

Recent studies by Blum and Roberts (M. D. Blum & Roberts, 2009) estimate a 60% decrease in sediment flux in the last ~60 years, while Bouche et al. (1994) show a 25% loss of wetland environments within the Mississippi delta. The problem is seen as so dire that

restoration projects in starting the 1990s (culminating in the 2017 a Coastal Master Plan) have been implemented to help curtail loss and damage to coastal wetland environments, making it the first of its kind in the world to address the colossal human-induced changes to coastal Louisiana on the Mississippi Delta. It is because of these problems that this research seeks to understand the modern sediment transport dynamic of the Mississippi River using a suite of provenance indicators to determine the way in which the modern river moves material from source to sink.

Provenance indicators have traditionally been an effective way to characterize sediment transport in large river systems. They can be used in both geologically ancient and modern systems; however, they must follow a few criteria in order to be effective. A provenance indicator must directly represent the bedrock from which it is sourced and it must be relatively robust, i.e., resistant to chemical and physical weathering. Another stipulation for using provenance indicators is that the geologic terrane from which the sediment is sourced must be diverse enough to be able to distinguish source signatures. In this dissertation, zircon, apatite, and Nd-Sr isotopes are used to interpret sediment provenance from in the modern Mississippi River.

Zircon is a robust provenance indicator. It has been shown to be useful in a variety of dynamic continental-scale rivers such as the Pearl River, the Indus River, and a series of ancestral geologic basins (Alizai et al., 2011; Amidon, Burbank, & Gehrels, 2005; Zhao, Shao, & Qiao, 2015). In this study, zircon is used as a provenance tool to better understand how the coarse fraction (63-125  $\mu\text{m}$ ) of the Mississippi and its tributaries is transported from source to sink. To do this, detrital zircon U-Pb age spectra are analyzed from grab samples taken from each of the main tributaries of the Mississippi River and downstream in the main trunk throughout the river. This creates a downstream sediment contribution map for the Mississippi

and its tributaries, which can be assembled to understand the flux of the sand-sized fraction throughout the system. Given the possible lag of sand sized heavy minerals during fluvial transport, this study seeks to determine not only where the Mississippi River zircon are derived from, but whether or not modern alteration of the catchments has fundamentally changed the U-Pb age spectra of the system. The first chapter explores variability of flux within the modern system by comparing new data with previously dated modern samples (M. Blum & Pecha, 2014). Final tributary contributions are consequently unmixed to determine relative drainage contribution using the DZmix program to determine relative percent contributions of each tributary to the overall system (Sundell & Saylor, 2017).

The second part of this study investigates the viability of apatite Rare Earth Elements (REE) and trace element compositions as a provenance indicator in continental scale drainage systems. While previous studies on generalized source rock type groups and the Paleo-Volga show the promise of using apatite for provenance, this study takes these analyses a step further by introducing quantitative methods to identify both variability and source contribution in the Mississippi River drainage (Belousova, Griffin, O'Reilly, & Fisher, 2002; Morton & Yaxley, 2007). Large detrital samples can often mask data patterns due to the diversity in the sample; however, using smaller sample sizes often does not capture all variability found within samples with extensive geologic range (Pullen, Ibanez-Mejia, Gehrels, Ibanez-Mejia, & Pecha, 2014; Vermeesch, 2004). This study uses the Belousova et al. (2002) cladogram and known elements which correlate with apatite fractionation to discriminate between drainage sources. By doing so, we are able to create plots that inherently highlight the diversity between geochemical data for major Mississippi River tributaries. These data are then used in an inverse Monte Carlo to infer

percent contribution from each tributary to the main Mississippi River downstream from its southernmost confluence.

In the final chapter, Nd and Sr isotopes are used to explore shifts in provenance throughout the last 3 thousand years in the Mississippi River delta. A core from the Modern/Plaquemines delta is examined in concurrence with grab samples taken from the modern Mississippi River and its tributaries in an effort to determine if humans have altered the  $\epsilon\text{Nd}$  signature of delta sediment, specifically within the last 150 years. Samples from the modern Mississippi and its tributaries were taken to identify general Nd-Sr signatures for different regions of the Mississippi catchment. These values are then applied to samples taken from a 5 m core extracted from the delta, dated with radiocarbon, OSL, and  $^{210}\text{Pb}$  along with  $^{137}\text{Cs}$  in effort to investigate the variability of Nd through time.

The goal of this dissertation is to explore how the modern Mississippi River transports sediment from its tributaries to its delta using three independent proxies. By using a multi-proxy approach a more comprehensive picture of the Mississippi River and its transport pathways can be drawn and possible anthropogenic influence can be explored. It is important that we study these kind of broad questions given the rapid alterations being made to the fluvial environments in which humans occupy (J. P. M. Syvitski & Kettner, 2011). Given rising populations around the world and the increasing demands for water, hydroelectric power and flood control, human engineered structures are already having a significant global effect on coastal environments. This is especially important in deltas and coastal regions with high population densities. By understanding the modern dynamics of the large modern river systems, it might be possible to curtail or alter the changes to help rescue the disappearance of these coastal environments and communities.

## **CHAPTER 2. ZIRCON U-PB DATING COMPARISONS IN A HIGHLY ALTERED RIVER SYSTEM, MISSISSIPPI RIVER, USA**

### **2.1. Introduction**

Tectonic and climatic factors shape and develop river drainages by influencing the transport of sediment from source to sink within a given system. Analyzing sediment from within river basins can provide useful information about sediment provenance and constrain the relative contribution of source tributaries to the net load of the river. Data from modern river systems often serve as an analogue for interpreting ancient systems; however, recently humans have altered drainage basins, inherently changing the way in which rivers access and deliver sediment to the coast (J. P. M. Syvitski & Kettner, 2011; J.P.M. Syvitski & Milliman, 2007). The Mississippi River is the largest river in North America, with constant human occupation of the catchment for at least the last five thousand years. Blum and Roberts (2009) estimated a reduction in sediment delivery to the delta of 60% due in large part to damming of the upstream tributaries over the last 60 years. Given the degree of anthropogenic alteration to the modern sediment transport regime, it is important to understand 1) if U-Pb zircon dating results can be reproduced in large rivers and 2) if erosional signals in the form of zircon age population variability propagates from source to sink in historic times.

This study compares previously reported detrital zircon U-Pb ages to new data to elucidate the degree to which resolvable U-Pb age populations that are used for provenance studies fluctuate in anthropogenically altered systems. These ages are paired with both grain size analysis and bulk geochemistry to understand the possible causes of variation found between samples taken throughout the basin.

## 2.2. Regional Basement Rock Provinces

The use of zircon grains as provenance tools is based on the large-scale tectonic heterogeneity of the continental source areas, which in turn is related to the progressive accretion of these blocks through geologic time through phases of magmatism and crustal accretion. The Superior Province (2500–2700 Ma) formed as a result of several cratonic blocks colliding, specifically the Slave-Rae-Hearn and the Superior, to eventually form the North American craton (Hoffman, 1988)}. Zircon dates for the longest continuous greenstone belt in the Superior Province largely fall between 2600 and 2800 Ma (Corfu, Krogh, Kwok, & Jensen, 1989). Later the Trans-Hudson Province (1800-1900 Ma) accumulated the Hearn, Wyoming, and Superior Blocks to form the core of the Laurentian continent, which can be seen in the Black Hills of Dakota (Hoffman, 1988; Ross & Villeneuve, 2003; Dahl, Holm, Gardner, Hubacher, & Foland, 1999)

The Penokean province is comprised of a series of Archean and Paleoproterozoic rocks that reach from central Minnesota to Canada (Van Schmus, 1976), (Dahl, Holm, Gardner, Hubacher, & Foland, 1999; Davidson, 1995). This terrane contains igneous and metasedimentary rocks which later experienced metamorphism and deformation from arc accretion events and plutonic activity. These provinces have been regionally dated through both Nd and zircon to approximately 1800-1900 Ma (Bickford & Van Schmus, 1985) (Nelson & DePaolo, 1985).

The Yavapai/Mazatzal Province (1600-1800 Ma) is the basement terrane that underlies much of the western and mid-continental regions of North America. The Yavapai Province runs from Arizona to Minnesota and was formed as a result of multiple pulses of arc accretion (Bowring & Karlstrom, 1990; K. Karlstrom, Bowring, & Reed, 1993; K. E. Karlstrom & Humphreys, 1998). According to Nd isotope data, this block shows little to no reworking of

Archean or Paleoproterozoic older crustal units (Donald J DePaolo, 1981). The Mazatzal Province formed directly after the Yavapai and stretches from northern Mexico, through the southwest United States into Canada. This terrane formed in a continental active margin which and was affected by arc accretion and the accumulation of back arc supracrustal sequences (Heslop et al., 1999; K. Karlstrom et al., 1993).

The Granite-Rhyolite and Grenville Provinces can be found at depth from the Southwest and across the eastern United States. The Granite-Rhyolite Province is focused in the Midwest but may extend further into areas of New York (Bickford & Van Schmus, 1985; Muehlberger, Denison, & Lidiak, 1967). It is dominated by intrusive A-type granites which may have been orogenic in origin (McLelland, Daly, & McLelland, 1996), (Corrigan & Hanmer, 1997), (K. E. Karlstrom et al., 2001). The Grenville Province (1000–1200 Ma) stretches from Texas and parts of Mexico across eastern North America. This terrane is the result of prolonged collisions which assembled the Rodinia Supercontinent (Moore, 1991); (Dalziel, 1991).

The Appalachian/Suwannee/Wichita Block as defined here represents several terranes that date to a similar time period. The Appalachian Province was constructed as a series of collisional events fused terranes onto Laurentia (Drake Jr, Sinha, Laird, & Guy, 1989; Horton, Drake, & Rankin, 1989). While there is strong evidence for recycling of zircon in these areas, a signature of about 500-700 Ma characterizes the Acadian clastic wedge (Park, Barbeau Jr, Rickenbaker, Bachmann-Krug, & Gehrels, 2010). The Suwannee Province accounts for Gondwanan accumulations that make up the basement of the Florida Peninsula and yield a zircon population of ages from 515 to 637 Ma (Mueller et al., 1994). While the Mississippi drainage does not venture as far south as the Suwannee Province it does capture the Wichita Igneous

Province in Southern Oklahoma. This province is associated with rifting that created the Southern Iapetus Ocean during the breakup of Rodinia 539-530 Ma (Hanson et al., 2013).

In this paper, we define the Cenozoic/Laramide region to represent the Laramide and Sevier mountain building events, which yield young zircon ages ( $<275$  Ma), despite also affecting much older tectonic basement blocks. It is important to note that there are several regions from which  $<400$  Ma zircons could be derived within the Mississippi basin. However, Whitmeyer and Karlstrom (Whitmeyer & Karlstrom) recognize that a Northern Rocky Sevier/Laramide Basin zircon signature, dominated by 30–275 Ma grains, overlies the Wyoming Block in the upper reaches of the Missouri River (Fan et al., 2011) (Fuentes, DeCelles, Constenius, & Gehrels, 2011) (May et al., 2013), (Craddock & Kylander-Clark, 2013). We demonstrate that this area is the primary source of  $<300$  Ma grains in the catchment.

### 2.3. Geologic Setting

The Mississippi River is the fourth longest drainage system in the world, reaching from Canada and flowing southward for almost 4000 km, before eventually emptying into the Gulf of Mexico (J.P.M. Syvitski & Saito, 2007). It is the largest drainage basin in North America with five main tributary systems that reach from the Appalachian Mountains in the east to the Laramide Orogeny in the west (Fig 2.1). Because the Mississippi River spans a variety of geologic terrains, it is ideal for understanding both continental-scale geologic and anthropogenic processes.

Figure 2. 1 Map of the basement tectonic blocks and associated zircon ages of North America. The major tributary catchments are outlined with dashed black lines, while sample locations are indicated by stars. 1) Upper Mississippi sampled above St. Louis (Upper), 2) Illinois River (Illinois), 3) Missouri River (Missouri), 4) Mississippi sampled south of Missouri, Illinois, and Upper Mississippi confluence (S. of Missouri), 5) Ohio River (Ohio), 6) Mississippi sampled south of the Ohio confluence (S. of Ohio), 7) Arkansas River (Arkansas), 8) Mississippi sampled south of Arkansas confluence (S. of Arkansas), 9) Red River (Red), 10) Mississippi River sampled south of confluence with Red River (S. of Red). Map modified from Gehrels (2014).

The Upper Mississippi River constitutes that stretch of the river that runs from Minnesota to Cairo, Illinois (Fig 2. 1), while the Illinois River drains parts of Illinois, Ohio, and Wisconsin and connects with the Upper Mississippi just north of St. Louis. The Upper Mississippi River

drains basement rocks from the Superior Province (2500–2700 Ma), Yavapai/Mazatzal Province (1600–1760 Ma), and Eastern Granite-Rhyolite Province (~1470 Ma) while the Illinois River exclusively drains the Eastern Granite-Rhyolite Province (Fig 2. 1).

The Missouri River is the longest river in North America and, in the past, has supplied the most suspended sediment to the Mississippi (Meade & Moody, 2010). The Missouri drains from Canada and the western United States to St. Louis, Missouri, and was formed following the Last Glacial Maximum (LGM). The retreat of the Pleistocene ice sheets blanketed the area with loess and glacial deposits, which contribute greatly to the sediment fertility of the river valley and its extensive agricultural development (Andrea Fildani, Hessler, Mason, McKay, & Stockli, 2018; Otvos, 1975). In general, the Missouri River contains a cornucopia of basement rock types including those of Mesozoic-Cenozoic magmatic provinces and the Laramide orogeny to older Archean crust (Gehrels, 2014; Iizuka et al., 2005). Prior to the LGM the Missouri River contributed much less material to the net flow into the Gulf of Mexico as a result of ice damming and stream rerouting (Andrea Fildani et al., 2018). During the LGM erosion and sediment flux from Cordilleran magmatic provinces and the Canadian Shield was more important compared to the modern drainage (A. Fildani et al., 2016).

The Ohio River and its tributaries drain most of the eastern and southeastern United States. It joins the Mississippi River at Cairo, Illinois and is, by water volume, the largest tributary of the Mississippi. The Ohio River formed in the Pliocene after ice dam failures around 3 Ma (Wayne, 1952). The basement rocks that the Ohio derives its sediment from mainly comprise those of the Grenville (1000–1200 Ma) and the Eastern Granite Rhyolite terranes (Fig. 2.1).

The Arkansas and Red Rivers derive their headwaters from the Rocky Mountains and flow from west to east across the continental North America. The Arkansas River headwaters lie in the Rocky Mountains and then flows across the northern edge of the Paleozoic Ouachita Orogen eventually joining the Mississippi near Napoleon, Arkansas. The source of the modern Red River lies near Harmon, Oklahoma and has ceased being a tributary to the Mississippi since the construction of the Old River Control Structure in 1963 (Meade & Moody, 2010). The sediment for the Red River is now diverted to the Atchafalaya Basin, along with 30% of the Mississippi River discharge, forming the Wax Lake delta (Roberts, Coleman, Bentley, & Walker, 2003).

#### 2.4. Sediment Transport and Provenance

Determining the provenance of sediment in large drainage basins can often be an arduous and complicated process. Large river systems, such as the Mississippi, often buffer sediment through temporary storage, erosion and intermittent transport (Nittrouer, 2011)}. Buffering in this context means the stabilization of the net flux to the ocean due to temporary storage and recycling of sediment between source and sink, eliminating short-term fluctuations and direct transfer to the basin of the erosional signal (Allen, 2008a, 2008b; Romans, Castelltort, Covault, Fildani, & Walsh, 2016).

In an unaltered system, sediment would be eroded from the upper basin and subsequently delivered to the delta. During transport, sediment would be captured and stored in large floodplain and point bar systems. The terrestrial delta would also provide storage for large amounts of sediment through distributary systems along the coast (H.H. Roberts, 1997). Transport and storage of sediment through a large river system can be complicated by the

behavior of different grain size in suspension and bedload. Fine grained clay, silt, and sand are usually transported as the suspended sediment load; however, zircon largely travels by bedload transport, and thus moves more slowly between source and sink. For example, U-series isotopic work in the Ganges suggests that the coarse-grained part of the sediment load takes approximately 80,000 years to travel from the source to the delta (Granet, Chabaux, Stille, France-Lanord, & Pelt, 2007). Studies of detrital zircon U-Pb ages in the Mississippi show responses times to environmental forcing of  $10^{3-4}$  yrs (A. Fildani et al., 2016; Mason et al., 2017), implying rapid transport times of that order of magnitude within this system and contrasting with model prediction (Castelltort & Van Den Driessche, 2003; Paola, Heller, & Angevine, 1992). This lag effect may be curtailed in modern river systems where levees confine and shuttle sediment more efficiently through the river channel.

In the modern Mississippi, previous studies have argued that most of the sediment is derived from the Missouri River (56.9 Mt/yr, 40.5% of total), while the largest portion of the water discharge is from the Ohio (24000 m<sup>3</sup>/s compared to 8000 m<sup>3</sup>/s in the Missouri) (Alexander, Wilson, & Green, 2012; Meade & Moody, 2010). Despite this high discharge, the Ohio accounts for only 32.5 Mt/yr of sediment flux, 23.1% of the total. Resolving the contribution of the Ohio in the final depocenter of the Mississippi River is, however, complicated since the dominant Grenville U-Pb population is also shared with the Upper Mississippi and Illinois River in particular. The last hundred years have seen the Mississippi River effectively cut off from its floodplains and distributaries due to the construction of large levee systems that span from the Upper Mississippi to the coast. Evidence presented by Heimann et al. (2011) shows a sharp decrease in the total suspended river sediment load after damming, largely in the 1950s (Fig. 2.2). This along with the construction of the Old River Control Structure coincides with a

60% reduction in sediment delivered to the delta (M. D. Blum & Roberts, 2009). While the data points to a significant reduction in fine-grained sediment transport, it does not appear that the sand is affected in the same way. Nittrouer and Viparelli (2014) show that sand impoundment behind dams is not affecting the coarse bedload supply because the Mississippi River scours enough of its own bed to maintain a constant supply. While dams are not seen to affect the overall sand supply of the Mississippi, the Old River Control Structure has completely cut off the Red River as a tributary, which must have impacted the provenance of the sediment downstream of this former confluence. Given the intense amount of anthropogenic alteration, it is important to understand if zircon U-Pb data taken from rivers like the Mississippi are representative of the stream over long time spans and if they are reproducible.

Figure 2. 2 History of suspended total sediment and sand loads in the Mississippi in the upper reaches from 1950 to 2010 after Heimann et al. (2011).

## 2.5. Sampling

Ten samples were taken from within the modern artificial levees of the Mississippi and its tributaries. Both coarse- and fine-grained facies were sampled across multiple beds to

counteract the effects of hydrodynamic sorting that can affect the concentration of zircons in any given sample (Fig. 2.1). Tributaries were sampled upstream of their confluences with the main trunk of the river, outside of the Modern/Holocene Mississippi river valley. Samples were also taken downstream from each tributary joining the Mississippi, to evaluate not only the input from each tributary but also the downstream transport and mixing of zircon in the modern system.

## 2.6. Methods

### 2.6.1 Bulk geochemistry and grain size

Hydrodynamic sorting can affect zircon age spectra, although studies to date suggest that there is no effect of the typically analyzed size fraction (63–125  $\mu\text{m}$ ) as a result of current sorting (Yang, Zhang, & Wang, 2012). To assess the impact of the sorting, bulk geochemistry was undertaken on all samples (Lawrence, Cox, Mapes, & Coleman, 2011). Zirconium concentrations have been used as a proxy for the relative abundance of zircon sand grains in any given sample (Amidon, Burbank, & Gehrels, 2005). These analyses can be used to compare the different samples in an effort to quantify outside factors that may be affecting zircon grain age populations.

The major element composition of the bulk sediment (all grain sizes) was analyzed by Inductively Coupled Plasma Emission Spectrometry (ICP-ES) at Boston University (BU), USA. Sediment samples were decarbonated with 30% acetic acid, washed with distilled and deionized water with a purity of 9–12 megaohms, and hand powdered at Louisiana State University (LSU) before total fusion preparation at BU. Glass beads for each sample were made in a muffle furnace at 1050°C by fusing  $100 \pm 0.5$  mg of sample mixed with  $400 \pm 0.5$  mg lithium

metaborate (LiBO<sub>2</sub>). The melted mixture was then dissolved in 5% HNO<sub>3</sub>, sonicated, manually shaken until no visible grains were observed, and further diluted for analysis (Dunlea et al., 2015). Precision for all elements was better than 1% of the measured value, and accuracy was confirmed by repeated analyses of International Standard Reference Materials (Basalt, Hawaiian Volcano Observatory, BHVO-2)(Wilson, 1997). Results of the geochemical measurements are shown in Table 1.

Table 1. Major Element Concentrations in wt % Oxide and Trace Elements in ppm

Sample Location	P <sub>2</sub> O <sub>5</sub>	SiO <sub>2</sub>	MnO	Fe <sub>2</sub> O <sub>3</sub>	MgO	Al <sub>2</sub> O <sub>3</sub>	TiO <sub>2</sub>	CaO	Na <sub>2</sub> O	K <sub>2</sub> O	Ba	Zr	Sr

## 2.6.2 Grain size Analysis

Grain size analysis followed the procedures of Hülse and Bentley (2012) and was completed on the bulk sediment sample (all grain sizes). A small amount of a sample was placed into a cleaned 50 ml plastic centrifuge tube and 5–7 ml of sodium metaphosphate solution was added. The tube was capped and vortexed to deflocculate clay-sized sediment and separate organic particles. The sample was poured through an 850 µm sieve and funneled into a 15 ml glass test tube. After centrifuging and removing the clear supernatant, 2–3 ml of sodium metaphosphate and 5 ml of 30% H<sub>2</sub>O<sub>2</sub> were added. Tubes were vortexed again and then put into a hot bath that was heated to 70°C. This step requires persistent monitoring to prevent loss of

reactant by spraying with acetone until the reaction stabilized. Reactants sat overnight in an effort to completely oxidize any organic matter. Reacted supernatant was then removed and 5 ml of sodium metaphosphate were added. Samples were then rinsed with deionized water, transferred into 50 ml plastic centrifuge tubes, and topped with sodium metaphosphate into a sample solution of up to 40 ml. Samples were vortexed again prior to grain size analysis. Grain size analysis was conducted on a Beckmann Coulter LS13 320 laser diffraction particle size analyzer at LSU. The obscuration of all running samples in the aqueous liquid module (ALM) was between 8–12 %.

### 2.6.3 Zircon Dating

Zircons were concentrated using heavy liquid methods; all age analysis for zircon was completed at LSU on an iCAP Q ICP-MS with a CETAC Technologies LSX-213 laser ablation system. Three standards were used: the Plešovice (337 Ma, (Sláma et al., 2008), Temora (417 Ma, (Black et al., 2003)), and 91500 (1065 Ma, (Wiedenbeck et al., 1995). For each sample, about 120 grains were analyzed in order to assure a statistically robust quantification of the age populations in a sediment derived from multiple sources (Vermeesch, 2004). Post-analytical processing of the data was completed in IGOR Pro using Iolite v.2.5 for data reduction. For zircon quality, a control of  $\pm 30\%$  concordance was used, with  $^{206}\text{Pb}/^{238}\text{U}$  ratios being used in grains younger than 1000 Ma and  $^{207}\text{Pb}/^{235}\text{U}$  ratios being used in grains older than 1000 Ma (Ludwig & Probst, 1998). Further data processing for the zircon age data was completed in R with the Provenance package of Vermeesch et al. (2016). The deconstruction of the zircon populations to determine mixing inputs and to derive comparisons between data were completed using the detrital zircon statistical comparative and mixing software Sundell & Saylor (2017). Analytical data is provided in Appendix A.

## 2.7. Results

### 2.7.1 Bulk Geochemistry

Bulk geochemistry of the sediment samples shows that these are quartz-rich sands when plotted against average continental crust values (Fig. 2.3). Calculation of the CIA (Chemical Index of Alteration) using the following formula:

$$CIA = \frac{Al_2O_3}{(Al_2O_3 + CaO + Na_2O + K_2O)}$$

indicate moderate levels of alteration (between 56 and 70), with the Ohio River showing the highest values and the Arkansas the lowest (Fig. 2.4).

Figure 2. 3 Plot of  $Al_2O_3/SiO_2$  versus  $Fe_2O_3/SiO_2$  for sediments from the Mississippi River after Singh et al. (2005). Lower ratios indicate increase of the quartz proportion and depletion of phyllosilicates. Linear trend corresponds to mineralogical sorting of these sediments during fluvial transport. Star corresponds to average Upper Continental Crust (UCC) (Taylor & McLennan, 1995) (Taylor & McLennan, 1995) (Taylor & McLennan, 1995) (Taylor & McLennan, 1995).

Most of the trunk stream values for the Mississippi River plot around values found in the Missouri River. In addition, Principle Component Analysis (PCA) was performed on the major element geochemistry in an effort to compare differences between samples (Fig. 2.5). Most of the elements have little variation between samples, however  $\text{Al}_2\text{O}_3$  and  $\text{SiO}_2$  are highlighted as being the most variable. The Red and Illinois River samples show the most variation in this aspect, with the Red River displaying relative  $\text{Al}_2\text{O}_3$  depletion and  $\text{SiO}_2$  enrichment (Fig. 2.5). The Illinois River conversely is relatively  $\text{Al}_2\text{O}_3$  rich and  $\text{SiO}_2$  poor. Despite these minor variations, when viewed as a whole, the bulk geochemistry data is relatively uniform (Fig. 2.3), suggesting that the samples are comparable to one another in terms of their general mineralogy and do not show many major differences driven by hydrodynamic sorting.

Figure 2. 4 Geochemical signature of the analyzed samples illustrated by a CN-A-K ternary diagram (Fedo et al., 1995). CN denotes the mole weight of  $\text{Na}_2\text{O}$  and  $\text{CaO}^*$  ( $\text{CaO}^*$  represents the  $\text{CaO}$  associated with silicate, excluding all the carbonate). A and K indicate the content of  $\text{Al}_2\text{O}_3$  and  $\text{K}_2\text{O}$  respectively. Samples closer to  $\text{Al}_2\text{O}_3$  are rich in kaolinite, chlorite and/or gibbsite (represented by Kao, Chl and Gb). CIA values are also calculated and shown on the left side, with its values are correlated with the CN-A-K. Samples from the Arkansas River have the lowest values of CIA and indicates high contents of  $\text{CaO}$  and  $\text{Na}_2\text{O}$  and plagioclase. Abbreviations: sm (smectite), pl (plagioclase), ksp (K-feldspar), il (illite), m (muscovite), bt (biotite).

Trace elements (Zr, Ba, and Sr) were also used to determine the heterogeneity of samples, because these too are often used as provenance tools (Bhatia & Crook, 1986; McLennan, Hemming, McDaniel, & Hanson, 1993). Water immobile elements in source bedrocks are transferred to the sediment and affect the bulk compositions of the mixed stream. Within this data set, Ba and Sr values are mostly stable, with the Zr values being the most variable (Table 1). South of the Red River, in particular, Zr content is low, implying a paucity of zircon content.

Figure 2. 5 Principal component analysis (PCA) based on the major and select trace element geochemistry of the bulk sediment samples considered in this study. The scatter in values shows that there is significant variability only for  $Al_2O_3$  and  $SiO_2$  in the sediments which we interpret to be largely driven by hydrodynamic sorting.

## 2.7.2 Grain size

Analysis of grain size also shows variation between samples (Fig. 2.6). Consequently, when Zr contents are plotted against mean grain size, there is an interesting link between the abundance of Zr and larger mean grain size (Fig. 2.7). Larger mean grain size is associated with lower Zr concentrations and thus fewer zircon grains in our sample set.

Figure 2. 6 Range of grain sizes as measured by laser particle size analysis methods for the samples analyzed for zircon U-Pb dates within the study (see Fig. 2.1 for sample locations).

Figure 2.7 Plot of Zr concentrations against mean grain size showing that samples with mean grain size  $>300 \mu\text{m}$  have low Zr contents.

Taking both the bulk geochemistry and grain size into account, there is little variation of most major elements (Table. 1) or in the level of chemical alteration (Fig. 2.4) between the headwaters and the Gulf of Mexico. There is, however, variability in grain size and the abundance of zircon between samples (Fig. 2.7).

### 2.7.3 U-Pb Zircon Results

Following the earlier study of Mason et al. (2017) and Blum & Pecha (2014), the zircon ages are broken down into seven population groups, which are deemed to be of significance to the provenance. The youngest is the Cenozoic/Laramide group (30–275 Ma)(Iizuka et al., 2005), followed by the Appalachian/Wichita/Swannee (380–650), Grenville (1000–1200 Ma), South and East Granite Rhyolite (1370–1470 Ma), Yavapai/Mazatzal (1600–1760 Ma), Trans-Hudson (1800–1900 Ma) and the Penokean/Superior Group (2500–2700 Ma) (Fig. 2.8). We find here the Missouri tributary is dominated by the younger zircon populations found in the Rocky Mountains. In contrast, the Red and Arkansas Rivers have a relatively smaller abundance of young zircon (<300 Ma) and also contain substantial populations of Grenville, Granite Rhyolite and Yavapai affinity. The northern tributaries (Upper and Illinois) have a large number of older Penokean/Superior and Grenville zircons. The samples from the main trunk of the Mississippi River (4,6,8, and 10; Fig. 2.8) all have a dominant young (<300 Ma) population, showing a strong downward propagation of Missouri/Rocky Mountain zircons throughout the modern system.

Figure 2. 8 Kernel density estimate (KDE) diagrams (Vermeesch et al., 2016) for the zircon U-Pb ages in the different samples considered in this study. Vertical colored bars show diagnostic ages associated with key tectonic blocks within North America and which form source terrains to the Mississippi. Also plotted are the data from Blum & Pecha (2014) as KDEs in dotted line next to our data to allow direct comparison. The similarity and likeness of the two samples were calculated using the Sundell & Saylor (2017) statistical package to show how the different analyses compare with one another.

## 2.8. Discussion

### 2.8.1 Bulk Geochemistry and Grain Size

The bulk geochemistry does not vary greatly between samples, as shown by the major element ratio (Fig. 2.3) and PCA plot (Fig. 2.5).  $\text{Al}_2\text{O}_3$  and  $\text{SiO}_2$  contents are the most variable, especially in the Illinois and the Red River (Fig. 2.5). If the samples were variably enriched in heavy minerals as a result of strong hydrodynamic sorting, they would show increased variability in  $\text{TiO}_2$ ,  $\text{Fe}_2\text{O}_3$ , and  $\text{MgO}$  which are abundant in mafic minerals. The samples addressed by this study are neither greatly enriched nor depleted in these elements, which implies that there is no significant hydrodynamic sorting affecting the bulk geochemistry. This conclusion, however, is somewhat complicated by the concentration of Zr found within the samples, which does show significant variance. As mentioned above, there is a relationship between grain size and the concentration of Zr in these samples. Samples with a mean grain size of over  $300\text{ }\mu\text{m}$  show significantly lower concentrations of Zr (Fig. 2.7). This specifically affects the samples from the Upper Mississippi and the Mississippi south of the Red River, which suggests that hydrodynamic sorting could be influencing the amount of zircon found within these samples. In general, these samples are relatively similar in bulk composition, but coarser in grain size, which is shown to have an effect on Zr content.

Although grain size may play some role in controlling zircon concentration, we also consider zircon fertility in the different source areas as a possible explanation for the discrepancy in Zr concentrations in the different tributaries. In some settings, such as the European Alps, the fertility of source rocks with regard to zircon can vary by up to three orders of magnitude (Malusa, Resentini, & Garzanti, 2016). However, in North America, it has been noted that Grenville age granites are especially rich in zircon ( $\sim 520\text{ ppm}$ ) and are not reset during later

orogenic events, leading to a bias in sediment budgets that do not account for this (David P. Moecher & Scott D. Samson, 2006). North American subduction-related granites are noted to have relatively low Zr (~150 ppm) in comparison (Dickinson, 2008). These differences should be reflected in the zircon concentrations in the tributaries. However, in this study the goal is to estimate the relative sediment budgets of the different tributaries, and, in particular, to determine the average zircon fertility of each catchment, which is achieved through analysis of Zr contents of the bulk sediment analyses.

Looking at fine-grained sediment, <200  $\mu\text{m}$ , there is a wide variation in Zr contents, suggesting significant variability in zircon fertility within the bedrock of the different tributaries. These vary as low as 58 ppm in the Upper Mississippi and as high as 791 ppm in the Red River (Table 1). If these truly reflected the abundance of zircon in these source regions, then a correction would have to be made to any mixing calculations. However, it is noteworthy that the Mississippi south of its confluence with the Red River has one of the lowest abundances of Zr, which suggests that hydrodynamic sorting, at least of zircon, may be just as important as fertility in controlling the concentration of zircon in any given sample (Fig. 2.7). Consequently, we are reluctant to apply a simple correction based on Zr concentrations because this would introduce as many errors as it might resolve. Specifically the Upper Mississippi sample is affected by hydrodynamic sorting with a mean grain size >300  $\mu\text{m}$ , resulting in its low Zr content. If this was considered a good regional average, then correcting for apparent zircon fertility would result in overestimation of the flux from this part of the basin. The importance of hydrodynamic sorting is also emphasized by the fact that the trunk Mississippi River itself (Mississippi south of the Red River) is generally lower in Zr compared to any of the tributaries from which it is derived.

### 2.8.2 Detrital U-Pb Zircon Populations

The different amounts of sand-sized sediment provided by the tributaries into the main Mississippi River can be assessed by looking at the relative proportions of the major populations of detrital zircon groups downstream of confluences between the headwaters and the Gulf of Mexico (Fig. 2.9). The upper reaches of the river are marked by mixing between the Missouri, the Upper Mississippi, and the Illinois, each with their own unique signature. Downstream of their confluence, there is a very large contribution from the Cenozoic/Laramide (30–275 Ma), which requires a dominant flux from the Missouri compared to the Upper Mississippi and the Illinois. Further downstream, as this mixes with the Ohio, which is dominated by Grenville-aged grains, there is comparatively little change downstream, suggesting that the Ohio's net contribution to the Mississippi is rather modest. Further downstream, mixing with the Arkansas River shows a marked increase in the proportion of Grenville (1000–1200 Ma) grains, which are also abundant in the Arkansas River. This implies significant sediment flux from the Arkansas tributary into the mainstream. In contrast, although the Red River also has a large proportion of Grenville grains, the net composition of the mainstream Mississippi does not change greatly downstream of this confluence (Fig. 2.9). This suggests the Red River is a relatively modest contributor to the total sediment flux, especially given the high Zr contents of the samples measured from this stream. A low flux from the Red River is consistent with the fact of the Red River is now separated from the main Mississippi by the Old River Control Structure, put in place in the 1960s, so that large volumes of sand are not expected to be added to the mainstream from that particular tributary since that time.

Figure 2. 9 Pie diagrams showing the breakdown of the zircon U-Pb ages for each of the samples considered in this study. Categories relate to age ranges considered diagnostic of key source terranes in the headwaters of the Mississippi. See Figure 2.1.

### 2.8.3 Sediment Mixing

The unmixing software of Sundell & Saylor (2017) allows for a statistical evaluation of the mixing process of the four tributaries downstream of each of the major confluences. This software uses the age composition of the individual tributaries upstream of the mixed sample in order to estimate the relative contributions from each river to generate the zircon population measured downstream of the confluence. Statistical calculations assume that each of the tributary samples is representative of the bedload flux from that particular branch of the river. The uppermost sample, just south of the Missouri, Illinois, and Upper Mississippi River confluence (Fig. 2.10A), shows a strong dominance of sediment derived from the Missouri River (73%) with very little being contributed from the Illinois (1%). It should be noted that the compositions measured in the Upper Mississippi and Illinois are very close to one another, making them hard to resolve (Fig. 2.8). Further downstream, as the Ohio River joins the Mississippi, the unmixing software estimates that only 2% of the bedload downstream of that confluence may be coming from the Ohio River. A slight increase in flux from the Illinois is not considered significant given the lack of separation between the Illinois and the Upper Mississippi, but with confidence assume both combined result in 26% bedload contribution. Figure 2.10C shows a much more significant change downstream of the Arkansas confluence. Here the model estimates up to 16% of the total load downstream of this point is derived from the Arkansas River. The Ohio and the Illinois both increase their relative flux downstream of the Arkansas-Mississippi confluence compared to upstream trunk river samples, which should not be possible. However, this calculation assumes that the river is in steady state and not susceptible to short-term variations, which would account for such variation.

Figure 2. 10 Downstream variation in flux from the major tributaries to the trunk stream of the Mississippi showing the mixing as each tributary joins the mainstream. The calculated contributions are derived from the un-mixing software of Sundell & Saylor (2017) using zircon age spectra from samples. See Fig. 2.1 for sample locations.

Again, the lack of separation between the Illinois and Upper Mississippi in terms of its zircon U-Pb age spectra may also be a factor in the apparent increase in sediment derived from the Illinois. The large flux from the Arkansas is of particular importance in this mixing model compared to earlier budgets based on water discharge and zircon mixing models (Mason et al., 2017).

Finally, when considering the sediment downstream of the Red River confluence, the contribution from that particular tributary is estimated to be quite low (4%). Again the material flux from the Arkansas River is relatively great (28% Fig. 2.10D), and is somewhat more than immediately downstream from its own confluence (16%) (Fig. 2.10C). This may be suggestive of short-term variations in the flux within the mainstream. Regardless of uncertainty in the Red and Arkansas Rivers, these analyses show that the Missouri is the dominant contributor, even in the lower reaches the river. We, however, emphasize the low contributions from the Red River and significant flux from the Arkansas River well into the lower reaches of the Mississippi River (Fig 2.10D).

#### 2.8.4 Controls on Continental Erosion

Having established the relative contributions of the different tributaries to the overall bedload flux into the Mississippi, it is important to consider why sediment production is distributed in this way. The Missouri River is, unsurprisingly, the most sediment-productive because it is also the largest tributary within the Mississippi basin and furthermore, it drains relatively high and steep topography in the Rocky Mountains. Erosion rates are known to increase sharply when local relief exceeds around 1 km (Burbank & Anderson, 2001). Because the Appalachian Mountains only locally exceed that value in total elevation above sea level, erosion rates might be expected to be consequently slow. In contrast, the Rocky Mountains are

much higher (>3 km) and have been more recently tectonically active, resulting in steep slopes in the headwaters and thus rapid erosion rates. The Missouri River further erodes easily mobilized glacial-era materials eroded from local bedrock and transported via rivers and wind to proximal plains in the form of loess and till (Otvos, 2015). It is significant that although the zircon budget for the Missouri River comprises around half Cenozoic/Laramide age grains, the area of its basin underlain by Laramide rocks is relatively small (Fig. 2.1). This requires that erosion in the Missouri River is focused in its uppermost (highest relief) reaches. The relative productivity of the Missouri River contrasts with that of the Ohio which, despite being a relatively large basin, is a small contributor to the overall flux. This is because the topography of the Appalachian Mountains is reduced and heavily eroded compared to that in the upper reaches of the Missouri. Although the average rainfall is much higher in the Ohio basin, this does not translate into higher erosion rates and this may partly reflect the widespread vegetated character of the basin, which reduces runoff and erosion, as well as the lack of high local relief (Burbank & Anderson, 2001). The Arkansas River, identified as being a significant source of sediment, also drains relatively steep source ranges in the central Rocky Mountains area, which is consistent with the greater contribution estimated here. It is not possible to assess the controls on erosion in the Red River basin because its influence has been curtailed by the installation of the Old River Control Structure. In general, steepness of topography in the sediment producing regions and size of the drainage basin are more important than climatic variability in controlling sediment flux within the Mississippi drainage. In addition, the erodibility of the sediment sources in west, particularly in the form of loose glacial era sediments, are subjected to seasonal rainfall and less vegetative cover, makes them even more susceptible to erosion. We further recognize that large areas within the Missouri and Arkansas basins have been cleared of the natural vegetation and are now

extensively utilized as agricultural land, which is susceptible to erosion through runoff and soil loss (Montgomery, 2007). The anthropogenic impact on the modern erosion pattern cannot be overstated.

#### 2.8.5 Reproducibility of Zircon Age Populations

In order to assess the robustness of the zircon U-Pb method in modern anthropogenically altered systems and to measure the amount of erosion and sediment productivity through the Mississippi basin, we compare our results with previously published analyses. These new data are compared to zircon dated by Blum & Pecha (2014), who analyzed many of these same tributaries, with slight differences in location of sampling (Fig. 2.1, 8, and 11).

The Upper Mississippi shows a close similarity between the new and existing analyses (Fig. 2.8 and 2.11). A crucial difference is that zircon dated by Blum & Pecha (2014) emphasize more strongly the importance of the Granite Rhyolite and Yavapai terrains to sediment production in the upper reaches. The Missouri River shows greater differences between the earlier work and the data presented here (Fig. 2.8). Both studies emphasize a Laramide peak, but the older ages of Grenville, Granite Rhyolite and Yavapai origin seen in the earlier work are less well represented in the present study. A similar result can be seen south of the Missouri-Mississippi confluence where our new data emphasize flux from the Missouri River (Fig. 2.8). Analyses of the Ohio River are remarkably similar between the two studies. Likewise, the Arkansas River yields a close match between the different data sets. Analyses from the Red River show some of the biggest disparities in age population between the two studies (Fig. 2.8). The earlier work emphasized a strong peak of Yavapai provenance that is not prominent in this study. However, our sample was taken further downstream, close to the Mississippi confluence,

compared to those in the Blum & Pecha (2014) study. In the lower reaches the two data sets are broadly comparable, although the Yavapai population is more strongly represented in the Blum & Pecha (2014) study, whereas the new data presented here emphasize a greater contribution from the Laramide.

Figure 2. 11 Multidimensional scalar diagram (MDS) showing the characteristics of the zircon ages analyzed in this study together with those from the earlier work by Blum & Pecha (2014). Figure is generated using the R program software from Vermeesch et al. (2016). Note that significant differences are seen between some samples but that the Ohio and Arkansas rivers shows significant similarities between the different studies.

To further quantify the differences between our data sets and earlier work, a multidimensional scaling diagram (MDS) was generated using the software package of Vermeesch et al. (2016)(Fig. 2.11). This allows an objective comparison of the age spectrum for each of the samples. In this diagram, samples with comparable zircon age spectra plot close together. The two analyses from the Ohio River are very similar to one another, as are those from

the Arkansas River and the Mississippi River south of its confluence with the Arkansas (Fig. 2.11). The diagram highlights the significant differences between our new analyses from the Red and Missouri Rivers compared to earlier work. The Upper Mississippi also appears to have significant differences, although comparison using the Sundell & Saylor (2017) statistical package indicate a relatively high degree of similarity (Fig. 2.8). The MDS diagram exaggerates the differences between those samples.

The samples from the lower reaches, just south of the Red River, from this study and the earlier zircon dated by Blum & Pecha (2014) can be unmixed into their contributing tributaries using the Sundell & Saylor (2017) software package. These bedload results are presented alongside average suspended sediment load readings from the USGS for each major tributary found in Mason et al. (2017)(Fig. 2.12). For a more direct comparison the Illinois was omitted from source data for the unmixing because Blum & Pecha (2014) did not analyze this tributary. Furthermore, the Illinois zircon age spectrum is similar to the Upper Mississippi therefore making it difficult to distinguish between for unmixing given the similar age spectra (Fig. 2.8). Data are presented with and without the Red River as a source to better understand the effect of the Old River Control Structure on sediment flux in the Mississippi. The result of the inverse Monte Carlo (Saylor & Sundell, 2017; DZMIX) from samples derived just south of the former Red River confluence shows that in our data there is very little input from the Red (4%), while the sample dated by Blum & Pecha (2014) implies a significant contribution based on unmixing calculation (36%) (Fig. 2.12A). Although the USGS gauging data indicate high flux from the Red River (18%), this material is currently diverted into the Atchafalaya distributary, which now forms the Wax Lake and Atchafalaya delta.

Figure 2. 12 Estimated budgets for the net flux from the Mississippi River to the Gulf of Mexico showing observational suspended sediment discharge data as reported by Mason et al. (2017) and the inverse Monte Carlo calculated bedload contributions using the data from Blum and Pecha (2014) and this study. The upper row shows budgets including flux from the Red River, while those in the lower row are recalculated to exclude contributions from the source.

Although our data taken from immediately south of the confluence implies a rapid response to the sand load from the cutoff of the Red River, the Blum & Pecha (2014) sample taken further downstream near Baton Rouge does not. This implies that the river is either recycling older Red River material from its channel or that zircons from the Red River move relatively slowly through the Mississippi, delaying the downstream propagation of the cutoff to the Baton Rouge location. We further suggest that the very high apparent contribution from the Red River to the Mississippi, as estimated with the Monte Carlo from the zircon dated by Blum & Pecha (2014) could be a reflection of high zircon fertility, as estimated from the Zr content

(Table 1; Fig. 2.7). The Red River sample contains 791 ppm Zr compared to 294 ppm in the Mississippi upstream. If these values are representative, then the bulk sediment flux from the Red River would be ~2.7 times less than the zircon estimate of 36% reported here.

If we consider the river zircon budget excluding the Red River as a contributor, the relative percentages using the zircon dated by Blum & Pecha (2014) data are very similar to those derived from this study in respect to relative contributions of sand from the source tributaries (Fig. 2.12B). In this case, the major discrepancy with our budget is with the USGS gauging data, which shows a much greater flux of sediment from the Ohio than recognized by either of the zircon studies. We suggest that this is because the Ohio sediment load is dominated by finer grained suspended sediments measured by the USGS but not analyzed in this zircon study, which focuses on the sand fraction. In a similar way, the discrepancy between the zircon budgets and the gauging data in regards to the Arkansas River suggest that most of the sediment contributed by the Arkansas River is in the form of sand and not suspended material (Fig. 2.12A). This is not surprising given the strong contribution of sand provided by the young, mountainous western sources of the Mississippi basin.

## 2.9. Conclusions

This study shows the importance of hydrodynamic sorting in controlling the zircon populations and in particular the importance of grain size, as well as fertility. We recognize that the coarsest sands are relatively poor in Zr concentrations and thus in zircon grains. If the potential effects of sorting are to be properly accounted for, it is critical to measure grain size and bulk sediment geochemical analyses in addition to the U-Pb ages whenever considering this type of data.

Analysis of the zircon U-Pb ages in the Mississippi River system presented here show the importance of the Missouri River in controlling the total amount of bedload sediment reaching the Gulf of Mexico. We do, however, estimate that the Arkansas River is an important source of material, despite previous studies indicating a relatively modest contribution. In contrast, the Ohio River, despite its significant water discharge and suspended sediment load, is not a major contributor of zircon sand grains into the mainstream. This is highlighted even more by the fact that Grenville basement rock has such high zircon fertility, which should result in an increase of these detrital ages in the sample south of the Ohio confluence not seen in this study. Much of the sediment in the Missouri River is derived from Cenozoic/Laramide source rocks and this contribution is seen to propagate far downstream. While this Cenozoic/Laramide bedrock comprises only a small part of the Missouri basin, glacial reworking has provided a rich source terrane for the Missouri to access. This emphasizes the importance of young mountain building and glaciation events in controlling the sediment record in the final depocenter. Additionally, this pattern of sediment production could be compounded by the spread of agriculture across the western plains of the Missouri and Arkansas rivers, affecting the high contribution of these areas to the net sediment load of the Mississippi.

Comparison of our new data with earlier work on the Mississippi through KDE (Kernel Density Estimate) diagrams shows a reasonable comparison between the two (Fig. 2.8). This gives confidence that detrital zircon studies can be a valuable way of examining provenance in modern and ancient samples, even in significantly altered rivers. However, we recognize some important differences between the earlier work and our new data. In particular, our analyses have a much lower proportion of Yavapai grains and higher Cenozoic/Laramide content compared to modern zircon dated by Blum & Pecha (2014). Since this trend can be seen along the entire

river, this is not attributed to damming effects, but most likely represents short-term instabilities in the sediment flux of the Mississippi.

Our study further emphasizes the importance of anthropogenic processes in controlling the sediment in the mainstream Mississippi. For example, large differences in the unmixing Monte Carlo performed between our work and the zircon dated by Blum & Pecha (2014) (Fig. 2.12) indicate that installation of the Old River Control Structure has had a large influence on the bedload immediately downstream, but that this influence is slow in propagating further towards the Gulf of Mexico. This would imply relatively slow zircon transport rates, consistent with the high density of this mineral relative to many others in the sand fraction. Separating this influence from short-term pulses is not feasible based on the present data set alone. However, accounting for similar damming or river diversion effects in other drainage basins in other rivers could be critical for a realistic assessment of the sediment budget.

### **CHAPTER 3. REE AND TRACE ELEMENTS IN DETRITAL APATITE AS A PROVENANCE INDICATOR: A CASE STUDY OF THE MISSISSIPPI RIVER AND ITS TRIBUTARIES, USA**

#### **3.1 Introduction**

Apatite is found as an accessory mineral in metamorphic rocks, and in igneous rocks as a primary mineral, as well as in sedimentary rocks both as a diagenetic cement and in a detrital context (Belousova, Griffin, O'Reilly, & Fisher, 2002; Chang, Howie, & Zussman, 1996).

Apatite is relatively physically robust and ubiquitous in continental settings, thus it can be a useful as a tracer of the origin of detrital material based on its geochemistry. Apatite geochemistry has been useful as a provenance tool in a number of modern and ancient settings based on variability in both geochemical character and thermochronologic age (Belousova et al., 2002; Chew, Sylvester, & Tubrett, 2011; Fleischer & Altschuler, 1986; A. Morton & Yaxley, 2007; Naeser, Naeser, & McCulloh, 1989).

Popular provenance methods, such as U-Pb geochronology of detrital zircons, represent robust approaches for the determination of provenance; however, this method can be affected by significant source fertility and lack of source rock age variability (A. Fildani et al., 2016). In the Alps, zircon fertility of different source terranes has been shown to differ by 3 orders of magnitude (Malusa et al., 2016). Specifically in North America, granites associated with Grenville orogenic events have significantly more Zr concentrations than surrounding terranes (Dickinson, 2008; D.P. Moecher & S.D. Samson, 2006). Grenville zircon also suffer from recycling issues and have been redistributed across most of the eastern half of the North America, which has led to complications with interpreting source derivation (A. Fildani et al., 2016). In such settings, additional datasets need to be used to cross-check and interpret findings that are influenced by such complications (Gerdes & Zeh, 2006; Sevastjanova et al., 2011).

Apatite geochemistry has the potential to contribute to provenance analyses due to its distinct variability between host rock types and its ability to characterize specific source regions in independent ways (Belousova et al., 2002; Fleischer & Altschuler, 1986; A. Morton & Yaxley, 2007). Belousova et al. (2002) provided one of the groundbreaking studies for this kind of analysis, using geochemical data to independently determine specific rock types of igneous apatites through a series of geochemical concentration thresholds. Morton and Yaxley (2007) studied the Paleo-Volga, which has a comparable geographic scale to the Mississippi River drainage, and they derived some useful interpretations regarding the provenance by using a variety of methods and element thresholds from past studies. That study was one of the first to examine detrital apatite use in provenance and determine its effectiveness as an independent tool to interpret source contribution through time. Sample sizes Morton and Yaxley (2007), however, were small ( $n = 19-52$ ) which has been shown to be detrimental for provenance studies using detrital zircon (Vermeesch, 2004).

This study seeks to further advance the methods used in Belousova (2002) and Morton and Yaxley (2007) through quantitative analysis in order to determine whether apatite can effectively be used to interpret provenance on a continental scale using the Mississippi River Valley drainage basin as a test (Fig. 2.1). By using a larger sample size ( $n=85-168$ ) and applying a more quantitative approach, we seek to further the application of trace elements and Rare Earth Elements (REEs) as an independent provenance proxy for typical continental siliciclastic sediment. This new approach used both REEs and trace minerals to derive an apatite geochemical signature for each of the Mississippi's large tributaries. These signatures are then used to determine the provenance of a mixed sample taken from the Mississippi River just south of its last major confluence with the Red River and upstream of the river mouth. Using the

defined end members, we unmix the apatite population using a Monte Carlo approach and compare them with recent studies involving modern Mississippi River provenance.

### 3.2 Apatite Geochemistry

Previous studies have shown that apatite geochemistry is largely controlled by host rock type and the degree of fractionation (Belousova et al., 2002; Fleischer & Altschuler, 1986). Trace elements and rare earth elements (REEs) substitute for Ca in trace amounts with concentrations varying according to the whole rock SiO<sub>2</sub> content (Belousova et al., 2002; Chang et al., 1996). With increased fractionation Y, Mn, and heavy REEs (HREEs) content increases. Conversely, Sr, Th and light REEs (LREEs) deplete with greater amounts of fractionation (Belousova et al., 2002; Chang et al., 1996; Nash, 1984). Furthermore, negative Eu anomalies increase with fractionation due to the depletion of Eu through the crystallization of feldspar (Budzinski & Tischendorf, 1989).

Belousova et al. (2002) used laser ablation inductively coupled-mass spectrometry (LA-ICP-MS) to characterize apatite REE and trace element compositions by source bedrock type and devised an apatite classification cladogram to discriminate apatite by rock type based on concentration thresholds for different elements. Bouch et al. (2002) and Morton and Yaxley (2007) investigated the geochemical composition of apatites from sandstones to understand authigenic diagenetic processes and constrain detrital provenance. Earlier studies generally used cross-plots to compare Sr/Y, Sr/Mn and Th/U ratios in order to discriminate source rock type.

### 3.3 Methods

#### 3.3.1 Laser ablation ICP-MS analysis

Sand samples were taken from each Mississippi River tributary and from the Mississippi River just south of its confluence with the Red River. They were then sieved and apatite grains between 63 and 150 micron in size were concentrated using heavy liquid methods and hand-picked. Laser ablation analysis of REE and trace elements was completed at in the Department of Geology and Geophysics at LSU on an iCAP Qc ICP-MS connected to a CETAC Technologies LSX-213 laser ablation system (Appendix B Supplemental Table 2.1). The NIST 612 glass standard (Pearce et al., 1997) was used for calibration. Due to the lack of international recognized apatite standards for REE and trace element concentrations, we used two in-house standards for assessing precision and reproducibility (Appendix B Supplemental Table 2.2). Post-analytical processing of the ICP-MS data was completed with IGOR Pro using the Iolite REE and Trace package. Results of the analyses are provided in Table 1 For each sample, approximately 120 grains were analyzed to account for lithologic variability found within each detrital sample and reflecting the potential multi-source origin, consistent with statistical methods used for interpreting detrital zircon (Vermeesch, 2004). REE data was chondrite normalized to account for the Otto-Harkins effect using the chondrite values from McDounough and Sun (1995). Eu anomalies ( $Eu/Eu^*$ ) were calculated chondrite normalized values with the following formula:

$$Eu/Eu^* = Eu / ((Sm + Gd) / 2)$$

### 3.3.2 Belousova Cladogram

Following Belousova et al. (2002), a cladogram was used to differentiate apatite from different types of source rock to the using a series of discriminating elements and element ratios (supplementary material, Fig 3.1). Based on this cladogram, apatite grains were separated into seven source rock categories: Lherzolite, Larvikite, Jacupirangite, Iron Ore, Granitoid, Dolerite, Carbonatite and Granite Pegmatite.

### 3.3.3 Monte Carlo Unmixing

Monte Carlo population simulations are often used in unmixing models for detrital zircon U-Pb age spectra (Sundell & Saylor, 2017). These types of analysis have been found to be especially useful in continental scale highly recycled populations and while traditionally used in zircon have been modified to help interpret apatite data in this study. In general, this modeled simulation predicts a best fit mixing model through repeated iterations of random sampling within categorically organized data (Sundell & Saylor, 2017).

To further interpret the geochemical dataset of the detrital apatites, a Monte Carlo population simulation was completed in MATLAB. We use an inverse Monte Carlo to essentially unmix large numbers of detrital apatite grains based on 1) La-Y-Sr geochemical proportions and 2) categorical source rock data. A program was designed to retro-source detrital apatite samples from specific tributaries by creating randomly generated weighted populations that were then compared to a mixed sample a user specified number times (we use 1000). Each of these generated populations was then compared to the known values of the mixed sample with a KS (Kolmogorov-Smirnov) test with a failure cutoff at user set 0.05 to determine the best fit or optimal unmixing model producing percent contribution from each tributary.

### 3.4. Geologic Background

#### 3.4.1 Precambrian shield

Apatite, like all provenance indicators, requires large-scale bedrock heterogeneity of the potential continental source areas to be useful in determining the geographical source of sediment to the final depocenter. The Mississippi drainage basin spans a variety of North American source regions that have complex geological histories. In particular, progressive accretion of tectonic blocks through geologic time led to different phases of magmatism and crustal accretion. This is reflected in a mosaic of different geological provinces in North America (Fig. 3.1) which potentially have unique apatite geochemical fingerprints.

The Superior Province (2500–2700 Ma) is part of the Archaean Craton and formed as a result of the Slave-Rae-Hearn and the Superior Blocks colliding and eventually forming the North American craton (P.F. Hoffman, 1989). Later the Trans-Hudson Province (1800–1900 Ma) amassed the Hearn, Wyoming and Superior Blocks to form the core of the Laurentian continent (Dahl et al., 1999; Paul F Hoffman, 1988; Ross et al., 2005). The Penokean Province is comprised of a series of Archean and Paleoproterozoic rocks that reach from the northern United States to Canada (Dahl et al., 1999; Davidson, 1995; Van Schmus, 1976). These terranes have been regionally dated through both Sm-Nd and zircon U-Pb methods to approximately 1800–1900 Ma (Bickford & Van Schmus, 1985; Nelson & DePaolo, 1985) and are drained by the northern reaches of the Ohio and Missouri Rivers, as well as the entirety of the Upper Mississippi River.

Figure 3. 1 Map of continental North America showing major surface crustal provinces of the bedrock divided by major age grouping. The outlines of the major tributary catchment defined in this paper are shown by dashed lines. Black stars show sample locations. Simplified and modified from (Garrity, 2009). The lower map indicates major continental block source terrane underlying surficial geology modified from Gehrels(2010).

### 3.4.2 Proterozoic midcontinent regions

The Yavapai and Mazatzal Province (1600–1800 Ma) is the basement terrane which underlies much of the western and mid-continental regions of North America. It spans from Arizona to Minnesota and formed as a result of multiple pulses of arc accretion (Bowring & Karlstrom, 1990; K. Karlstrom et al., 1993; K. E. Karlstrom & Humphreys, 1998). Nd isotope data indicate that the Yavapai Province experienced little to no reworking of Archean or Paleoproterozoic crustal units during its formation (Donald J DePaolo, 1981). The Mazatzal Province formed directly after the Yavapai and stretches from northern Mexico into Canada. This terrane formed in a continental active margin setting as a result of arc accretion and the accumulation of back-arc supracrustal sequences (K. Karlstrom et al., 1993; Shaw & Karlstrom, 1999). Rocks of this terrane are now largely covered by Cenozoic sequences.

The Granite-Rhyolite and Grenville Provinces are located in the Southwest and Eastern United States. The Granite-Rhyolite Province is extensive in the Midwest but extends further into areas of Canada (Bickford & Van Schmus, 1985; Muehlberger et al., 1967). It is dominated by intrusive A-type granites which may have been orogenic in origin (Corrigan & Hanmer, 1997; K. E. Karlstrom et al., 2001; McLelland et al., 1996). The Grenville Province (1000–1200 Ma) stretches from the southwest and across eastern North America. This terrane is the product of prolonged collisions which assembled the Rodinia Supercontinent (Dalziel, 1991; Moores, 1991). It is now largely covered by sedimentary passive margin marine and clastic sedimentary rocks (Fig. 3.1).

### 3.4.3 Phanerozoic orogens

The Appalachian and Ouachita terranes represents several terranes that date to a similar time period from 500-700 Ma. The Appalachian terrane was constructed during a series of collisional events with Laurentia (Drake Jr et al., 1989; Horton et al., 1989). The Ouachita Igneous bedrock is associated with rifting that created the Southern Iapetus Ocean during the breakup of Rodinia at 539–530 Ma (Hanson et al., 2013). The Appalachian and Ouachita terranes are shown as Paleozoic folded rocks in Figure 3.1

The younger Mesozoic and Cenozoic rocks associated with the Western Cordilleran Province of North America are associated with the building of the Rocky Mountains and have been proposed to account for a large amount of the sediment in the Missouri and Mississippi Rivers (Gregory, Herrmann, Ireland, & Clift, 2018, in review; also see Ch.2).

## 3.5. Results

### 3.5.1 Apatite by Source Rock Type

The most abundant types of apatite found in our samples are assigned to the Granitoid, Dolerite, Carbonatite, Granite Pegmatite and Iron Ore source types (Fig. 3.2, 3, and 4). For this reason, only these were plotted because there are too few apatite analyses assigned to Lherzolite, Larvikite or Jacupirangite source rock types to be statistically meaningful. Nonetheless, these data are provided in Appendix B for reference.

#### 3.5.1.1 Rare Earth element geochemistry

Chondrite-normalized REE plots of the different apatite source rock groups divided by the Belousova (2002) cladogram were created from a select few samples to demonstrate their general character, given the large sample size within each of the main categories (Fig. 3.2).

Trends in REE data are better expressed by plotting La/Yb, which represents the overall slope of the REE curve, against La/Sm which is a proxy for the relative enrichment of the LREEs (Fig. 3.3).

Figure 3. 2 REE plots from the population of apatite divided by Belousova (2002) apatite source rock type and colored by basin. Purple represents the northern/upper Mississippi apatites, yellow the Missouri River, Green the Ohio River, and brown the Southwestern tributaries.

Apatites classified as Carbonatites (Fig. 3.3A) show moderate to high HREE depletion (low La/Yb and La/Sm values) and LREE enrichment (high La/Yb and La/Sm values). Dolerite-

derived apatites (Fig. 3.3B) show modest to high levels of HREE depletion, with little LREE enrichment.

Figure 3. 3 Cross plots of La/Yb against La/Sm for apatite grains divided by source rock type. (A) Carbonatite, (B) Dolerite, (C) Granite pegmatite, (D) Iron ore, and (E) Granitoid. Blue, Orange, and Red boxes indicate increasing levels of LREE and HREE depletion.

Granite Pegmatites (Fig. 3.3C) have the most distinctive REE signature within their apatites, with the majority of samples showing LREE depletion and a depletion of HREEs, with a generalized negative slope to the REE plot. A few of the apatite grains in this group are found to have moderate HREE enrichment. Iron ore derived grains fall into three main groups (Fig. 3.3D). The first group are apatites with LREE depletion and moderate HREE depletion. A second group comprises apatites with moderate LREE enrichment and HREE depletion, while a third shows strongly negative REE slope (Fig. 3.2) with high HREE depletion. Finally, Granitoid apatites cluster between 1 and 10 along the La/Yb axis and 0 and 2 on the La/Sm axis (Fig. 3.3D), showing LREE depletion and moderate HREE depletion. A second group within the Granitoid population exhibits high HREE depletion.

#### 3.5.1.2 Ternary Diagrams

Since previous studies have found that trace elements such as La, Y, Sr, Mn and REEs change in relative proportions in apatites from different source rocks. Three of these elements were chosen to demonstrate variability in source rock type within the sample (Belousova et al., 2002; Chang et al., 1996; Nash, 1984). Y and Sr were chosen to plot because they had the highest variability among the trace elements, and they should, in theory, inversely vary with changes in fractionation. La was also chosen because, within the REEs elements, it displays the most variability and is therefore considered here as an analog for relative LREEs enrichment or depletion. Another reason for choosing these three elements is that, for the most part, La, Y and Sr have similar date ranges and generally plot well on a ternary diagram. Results were not normalized before plotting; however, plotting concentration values on a ternary diagram allows for in sample standardization between elements since they are scaled to relative proportions (Fig 3.4).

Figure 3. 4 Ternary diagrams plotting La, Y and Sr for apatite grains divided by rock type source. (A) Carbonatite, (B) Dolerite, (C) Granite pegmatite, (D) Iron ore, and (E) Granitoid. Red colors represent a high density of points while blue represents a low density.

Ternary plots show distinct differences in apatite by rock type (Fig. 3.4). Carbonatite apatites generally have high Sr concentrations and low concentrations of both La and Y (Fig.

3.4A). Dolerite apatites plot more in the center of the ternary diagram, with moderate to high concentrations of Sr and moderate levels of both La and Y (Fig. 3.4B). The Granite Pegmatite apatite population has a very distinctive signature showing enrichment in Y compared to La and Sr (Fig. 3.4C). There is another distinctive clustering within the Granite Pegmatite group that shows moderate levels of both Sr and Y, but overall granite pegmatite apatites are characterized by La depletion. Iron ore apatite grains (Fig. 3.4D) fall into three distinct groups with the largest group characterized by moderate levels of Sr and La, as well as Y depletion. While there is some overlap between Dolerite and Iron Ore apatites, the main Dolerite group tends to tighter clustering. A second group within the Iron Ore apatites has Y enrichment, with relatively low levels of La and Sr. Granitoid apatites (Fig. 3.4E), a catch-all felsic category, show the greatest degrees of variation and are harder to classify using this ternary plot.

### 3.5.2 Apatite Provenance

#### 3.5.2.1 Apatite by Tributary

For this study, apatite grains were divided into four main provenance groups related to different geographic areas of the Mississippi River catchment (Fig. 3.1 and 5); Northern tributaries, Missouri River, Southwestern tributaries (i.e., the Red and Arkansas Rivers) and the Ohio River. Morton and Yaxley (2007) previously used a series of cross-plots to show geochemical differences between apatite grains.

However, these graphs often fail to identify distinctive populations, especially when dealing with numerous, highly geochemically variable detrital grains, which are common when the drainage system is at the continental scale (Fig. 3.5, 6; see also Supplementary Figs. 3.2 and 3.3). Within these graphs, apatite grains show too much geochemical variation to be able to distinguish

coherent patterns that can be used to constrain provenance (Fig. 3.5). The only exception in our dataset is the Missouri River, where it appears that the apatites tend to plot towards the alkaline field around the iron ore end member (Fig. 3.5).

Figure 3. 5 Cross plots of La/Nd versus (La+Ce)/REE (total) divided by tributary. (A) Missouri, (B) Northern Tributaries, (C) Southwest Tributaries, and (D) Ohio. Numbers next to crosses represent average values of apatite from different rock type taken from (Belousova et al., 2002).

Figure 3. 6 Cross plots of Sr against Y concentrations for single apatite grains with fields showing the predicted source rock types from (A. Morton & Yaxley, 2007) and (Belousova et al., 2002), divided by tributary. (A) Missouri, (B) Northern Tributaries, (C) Southwest Tributaries, and (D) Ohio.

However, multidimensional statistical tools, such as PCA, appear to highlight differences within these detrital samples, especially when applied within the nomenclature framework of the Belousova et al. (2002) cladogram. Based on this cladogram, the major tributary areas were separated by rock type and then plotted as pie graphs (Fig. 3.7). The Missouri River appears to derive most of its apatite grains from Iron Ore, Dolerite, and Granitoid sources. What is specific to this drainage is the large amount of Iron Ore-derived apatite within the population (Fig. 3.7A).

When divided into different types of source rocks, the Northern Tributaries and the Ohio River have almost identical populations (Fig. 3.7B,D). This is interesting given that their geochemical signatures mapped on the ternary plots (of La, Y, and Sr) show such striking differences (Fig. 3.8). The Southwest Tributaries are dominated by Granite Pegmatite grains, having twice as many as any of the other drainage (Fig. 3.7C).

Figure 3. 7 Pie diagram showing the proportion of apatite grains derived from each rock type source divided by tributary, (A) Missouri, (B) Northern Tributaries, (C) Southwest Tributaries, (D) Ohio, and (E) Lower Mississippi.

Figure 3. 8 Ternary diagrams plotting La, Y and Sr for individual apatite grains separated by tributary. (A) Missouri, (B) Northern Tributaries, (C) Southwest Tributaries, (D) Ohio, and (E) Lower Mississippi. Red colors represent a high density of points while blue represents a low density.

Ternary plots were created for each tributary showing distinct differences between the main drainage areas of the Mississippi. The Missouri River shows a distinct grouping of apatite grains that show Y depletion and moderate levels of both Sr and La (Fig. 3.8A). When we compare this to the ternary plots of apatites divided by source rock type (Fig. 3.4), the Missouri apatites tend to plot strongly towards Iron Ore and Dolerite end members. The Northern Tributaries are slightly more diverse in terms of their apatite chemistry but have two resolvable main groups (Fig. 3.8B): one with Sr enrichment with moderate to low levels of La and Y, while the secondary grouping has Y enrichment with La and Sr depletion. The diversity found within the population is likely attributed to the large degree of geochemical variability in the Granitoid-related apatite found within the sample. The data suggests a diverse source composition. Apatites from the Southwestern tributaries have a rather diverse population but with a distinctive grouping of apatite grains that are enriched in Y and depleted in both Sr and La (Fig. 3.8C). When this ternary plot is compared to those in Figure 3.4 it can be seen that granite pegmatite apatites dominate the population. The Ohio River has one major grouping of apatite grains which are enriched in Y and depleted in both La and Sr (Fig. 3.8D). If this ternary (Fig. 3.8D) is compared to the La-Y-Sr ternary plot divided by source rock types (Fig. 3.4) it implies that the majority of grains in the Ohio River should be derived from Granitoid or Granite Pegmatite sources. A map showing the possible sources for each major apatite grain classification shows the distribution by tributary of Iron Ore, Carbonatite, Dolerite, and Granite Pegmatite source areas are later used to compare these findings (Fig. 3.9).

Figure 3. 9 Close-up map of the surficial bedrock cover found in Figure 3.1 showing possible apatite source rocks within each tributary catchment. Possible source rock locations compiled from several different sources (Hamilton, Goutier, & Matthews 2001; Krevor, Graves, Van Gosen, & McCafferty 2009; Landes, 1935; Schlische, Withjack, & Olsen, 2003; Tarr & McMurry, 1922; Woolley & Kjarsgaard, 2008)

### 3.5.2.2 Apatite in the Mississippi River

To test whether or not apatite can be used to decipher geochemistry at a continental scale, a sample was taken just south of the Mississippi's southernmost confluence, close to the river mouth. This sample was then plotted as a La-Y-Sr ternary (Fig. 3.8E), and the apatites were then divided into source groups that are presented as a pie plot (Fig. 3.7E). The La-Y-Sr ternary shows that the lower Mississippi River apatite population is represented by two major groups. The first group has moderate to high levels of Sr and La in relation to Y. The second group has

both Sr and La depletion relative to Y. Furthermore when apatite grains are divided into discrete apatite groups using the Belousova et al. (2002) cladogram, the Mississippi apatite population contains almost even amounts of Carbonatite, Granitoid, and Granite Pegmatite derived grains (Fig. 3.7E). Most notably, the lower Mississippi River contains a high number of apatite grains derived from Iron Ore, which is only seen to be dominant in the Missouri River (Fig. 3.7).

To more thoroughly explore the provenance of apatite grains in the Mississippi River, a statistical Monte Carlo unmixing model was applied to the apatite grains in two ways: 1) unmixing using the Belousova et al. (2002) cladogram categories, and 2) unmixing using the distribution in the La-Y-Sr ternary plots. When the apatite grains were divided based on the cladogram categories shown in Supplementary Figure 3.1, the percentage of apatite grains contributed from the Missouri River dominates at ~53% (Fig. 3.10B). Secondary contributions from the SW tributaries are at 27% with minimal input from both the northern tributaries and the Ohio River.

The same inverse Monte Carlo was applied to the La-Y-Sr ternary plots since they provide the most separation between both apatite grain types and source tributary compositions (shown previously in Figs. 3.4 and 8). Each ternary diagram was divided into 16 categories according to the different percentages of La, Y and Sr, then each grain falling within the those divisions were counted (divisions noted in Fig. 3.8 with black lines). Those counts were then used to create categorical datasets from which the Monte Carlo was constructed. The result of this Monte Carlo unmixing is displayed in Figure 3.10A. This shows the Northern Tributaries,

Southwestern Tributaries and the Missouri River as roughly equal contributors to the mixed lower reaches Mississippi apatite population.

Figure 3. 10 Pie diagrams showing the estimated contributions from the major tributaries to the lower reaches of the Mississippi River based on (A) Monte Carlo results from 16 apatite ternary groups, (B) Monte Carlo results from seven source rock groups, (C) USGS suspended sediment from gauging measurements (Mason et al., 2017), and (D) from zircon U-Pb age spectra (Gregory et al., in review; See Ch. 2).

### 3.6. Discussion

#### 3.6.1 Apatite Derived from Tributaries

The Missouri River has a distinctive cluster of apatites, as shown on the La-Y-Sr ternary plot (Fig. 3.8A). Furthermore, Missouri River apatites plot in the same part of the diagram as Iron Ore and Dolerite bedrock apatites (Fig. 3.4). The majority of the Missouri River apatites are Y-depleted with moderate levels of La, indicating less fractionated and more mafic/alkaline compositions (Figs. 3.8A and 3.5A). A recent study of zircon derived from the Missouri River catchment showed a relative lack of diversity in source rock that might explain the limited geochemical diversity seen in the ternary diagram (Fig. 3.8A) (Gregory et al., 2018, in review; see Ch. 2). Apatites from the Northern Tributaries of the Mississippi River show diversity in

their source compositions, with moderate to high levels of Sr for many of the grains and another minority cluster with high levels of Y (Fig. 3.8B). This pattern indicates erosion of apatites from a variety of sources. Both mafic and felsic sources are inferred from Figure 3.5B, but few grains are derived from alkaline sources. The mafic apatite grains in the Northern Tributaries are most likely derived from the Canadian Shield and Great Lakes region. We infer a high number of Granitoid-derived apatites based on the similarity between the ternary high density areas between the total population (Fig. 3.8B) and the granitoid only diagram (Fig. 3.11B). Given this association, it is apparent why many of the Northern Tributary apatites are classified as acidic on Figure 3.5B. The apatites from the Southwestern Tributaries of the Mississippi are dominated by a large group of grains with relative Sr and La depletions (Fig. 3.8C).

This is an indicator of high fractionation and erosion from felsic and metamorphic sources (Fig. 3.5C). The bulk of the apatite population from that part of the catchment is most likely derived from intrusive granite pegmatite sources within the southwest (Fig. 3.9). However, apatite grains from these rivers do show a broad variety of geochemical compositions and thus source rock bulk compositions, despite the concentration towards high Y contents. Previous studies of zircon U-Pb ages from the same catchment indicate a diverse basement rock provenance (Gregory et al., 2018; in review, see Ch. 2). Apatites from the Ohio River show La and Sr depletions with high levels of Y, which again likely indicates felsic and metamorphic source rocks (Fig. 3.8D and Fig. 3.9). Given the distinctive grouping and limited range of the Ohio apatite compositions shown in Figures 3.8D and 3.5D we suggest that these apatites are not derived from a great variety of sources. This finding is supported by multiple zircon U-Pb dating studies in that region (Gregory et al., 2018; Mason et al., 2017; D.P. Moecher & S.D. Samson, 2006).

Figure 3. 11 A) Missouri, (B) Northern Tributaries, (C) Southwest Tributaries, and (D) Ohio (E) Mississippi. Red color indicate high point density while blue colors represent low.

### 3.6.2 Apatite within the Mississippi River

When viewing the results for the inverse Monte Carlo for the Belousova et al. (2002) categories (Fig. 3.10B), the implied dominant flux from the Missouri River into the main stream is consistent with measurements of suspended sediment taken from USGS gauging stations of suspended sediment (Fig. 3.10C) (Mason et al., 2017). The relative contributions from the tributaries, however do not correlate very well. The differences between the Belousova et al. (Belousova et al.) categorical Monte Carlo results and the USGS sediment gauging results can either be attributed to temporally variable flux within the system, or a disconnect between suspended sediment and coarser bedload (Fig. 3.10B and 3.10C). Another issue that arises from running the Monte Carlo simulation on the cladogram categories is that the categorical data for each tributary must be relatively distinct in order to discern between populations. Lack of diversity can lead to possible overestimations from source with significant overlap. As seen in Figure 3.7, the Northern Tributaries and the Ohio River apatite populations are practically identical based on this analytical approach. This could explain the variation seen in the Ohio and Northern Tributary percentages between the Belousova et al. (Belousova et al.) unmixing pie diagram and those from the detrital zircon and Ternary (Fig. 3.10). It is for this reason that a second approach was applied by applying the inverse Monte Carlo to the results of the La-Y-Sr ternary diagrams.

When viewing the pie graph resulting from the inverse Monte Carlo applied to the La-Y-Sr ternary diagram (Fig. 3.10A), results closely resemble the relative contributions found in the detrital zircon U-Pb populations taken from the same grab sample and from detrital zircon studies in Mason et al. (Mason et al.). They, however, contrast with the USGS gauging data and results of the Belousova et al. (2002) categorical cladogram Monte Carlo results. The variability

between the two Monte Carlo unmixing models (Cladogram and Ternary) can best be explained by the limited variability resolvable between tributaries within the cladogram categorized apatite that were divided based on source rock type. The ternary diagrams were specifically designed to separate tributary populations and therefore produce a more region specific fingerprint with which the Monte Carlo can distinguish source contribution. What is interesting to note is the disconnect between the measured USGS suspended sediment flux and the apatite and zircon data (Fig. 3.10D) (Mason et al., 2017). It would seem that the suspended sediment within the Mississippi River is overwhelmingly dominated by the Missouri in comparison to the bedload sands. However, the bedload sands still account for a lion's share of the sediment flux, which can be seen in the deep sea fan both in the Pleistocene and Holocene (Andrea Fildani et al., 2018; A. Fildani et al., 2016; Mason et al., 2017).

Another important comparison is the difference that can be seen is between the detrital zircon and the ternary unmixing. The detrital zircon model estimates the Missouri contribution at 33.5% while the ternary slightly varies at 27.5% (Fig. 3.10D). This is one of the first provenance analyses of the Mississippi River bedload to show a less than dominant contribution from the Missouri River. The detrital apatite geochemical model may be capturing a decreased bedload flux from the Missouri due to the extensive damming of the river over the last 60 years (M. D. Blum & Roberts, 2009; Mason et al., 2017). This may have been missed by previous detrital zircon studies given the overlap of detrital zircon ages among the western tributaries of the Mississippi River.

Overall however, these methods seem to show that differences between the apatite U-Pb age analysis and apatite ternary unmixing are minimal and, going forward, could be used in tandem or independently to interpret provenance.

### 3.7 Conclusions

This study finds that apatite can be effectively used to interpret detrital apatite provenance based on the REE and trace element geochemistry chemistry from a population of grains. We found traditional methods of plotting the geochemistry of apatite grains to be limited when trying to fingerprint a detrital population with a large sample size. It is, however, interesting that, when plotting the 3 elements traditionally used to determine apatite variability (La-Y-Sr) in a ternary diagram, a geochemical fingerprint was able to be created for each tributary. This could then be linked to the Belousova et al. (2002) cladogram categories to define possible source rock within each tributary. By categorically dividing the data both with the traditional rock type categories from Belousova et al.(2002) and new ternary plot categories based on relative La-Y-Sr percentages, this study was able to produce mixing models that closely resembled those found from detrital zircon (Gregory, Herrmann, Ireland, & Clift, 2018). The Southwest tributaries are the largest contributor of bedload flux at 36%, with comparable contributions from the Northern Tributaries and Missouri at 33.5% and 27.5% respectively. As previously seen in other studies, the Ohio River contributes a modest amount at 3% (A. Fildani et al., 2016; Mason et al., 2017). Here we calculated a lower sediment flux from the Missouri River than previously reported, which could be one of the first provenance indicators showing the effect of damming on the Missouri River. By using a combination of both old and new methods, both trace elements and REEs are here confirmed as a useful tool for interpreting provenance of continental-scale detrital populations. This new approach can be used alongside or independent

of other provenance methods such as zircon and apatite U-Pb dating methods, and would be especially useful in situations where zircon is not a viable option,

## **CHAPTER 4. PROVENANCE OF ND ISOTOPES IN THE LATE HOLOCENE MISSISSIPPI RIVER DELTA**

### **4.1 Introduction**

Humans have changed the world and landscape in which they live, especially within the last 200 years. Many different scientific disciplines have shown these alterations to both atmosphere and climate (Montgomery, 2007; Ruddiman, 2003). In more recent years, geologists have also started to study the dynamic way in which human interactions have changed earth processes (Zalasiewicz, Williams, Steffen, & Crutzen, 2010). These alterations to the landscape disrupt the processes of the geosphere and hydrosphere both locally and globally. In particular, rivers and delta systems have been subject to some of the most dramatic changes (J.P.M. Syvitski & Milliman, 2007), e.g., the Pearl River (Hu et al., 2013). The Mississippi River is the largest in North America and has been populated since at least 9 ka with intensive settlement starting around 200–300 BP. This paper uses a delta sediment record to understand the dynamics between the natural and human processes that have impacted the Mississippi River drainage over the last 3 ky. To do this, we use Neodymium and Strontium isotopes from the tributaries and main trunk of the Mississippi to interpret the evolving provenance of the clay fraction in a well-dated core from the Mississippi River delta.

### **4.2 Neodymium as a Provenance Indicator**

Neodymium isotopic character is commonly used as a provenance indicator to understand siliciclastic dynamics within drainage basins. While other methods (such as U-Pb dating of zircon grains) are popular for coarse grained sediment, Sm-Nd and Rb-Sr radioisotopes have traditionally been used for the fine grained fraction (Bouquillon, France-Lanord, Michard, & Tiercelin, 1990; Clift & Giosan, 2012; France-Lanord, Derry, & Michard, 1993; Garzanti et al., 2011; Liu et al., 2017; Singh et al., 2008). Nd isotopes are particularly useful for provenance

studies because this isotope system does not fractionate during diagenetic processes or transport (S. L. Goldstein, O'Nions, & Hamilton, 1984). This means that Nd can be used as a direct representation of average source rock isotopic composition to interpret sediment provenance (S. J. Goldstein & Jacobsen, 1988; Steven L Goldstein & Hemming, 2003).

Nd isotope ratios ( $^{143}\text{Nd}/^{144}\text{Nd}$ ), commonly expressed as  $\epsilon\text{Nd}$  values (D. J. DePaolo & Wasserburg, 1976) are commonly used to distinguish between sediment eroded from terranes of different ages and/or petrogenesis. Rocks derived from the mantle in the deep geologic past have more negative  $\epsilon\text{Nd}$  values, while younger rocks have less negative or positive  $\epsilon\text{Nd}$  values. Younger rocks may also have negative values if they are formed by remelting of older material. Recent findings by Jonell et al. (2018) argued that the typical margin of uncertainty within bulk samples from the Himalayas resulted in a  $\pm 1$   $\epsilon\text{Nd}$  error. While rather large, this uncertainty most likely reflects the great variability found within samples and bedrock sources from the region, as well as the wide range in grain sizes. Previous studies addressing uncertainties within Nd isotope analyses that involved repeat analyses concluded that there was a  $\pm 0.6$   $\epsilon\text{Nd}$  uncertainty between samples (Chauvel, Bureau, & Poggi, 2010). When analyses have considered only the clay fraction, better reproducibility with smaller error has been achieved. Fine-grained sediments from South China Sea showed variations of  $\pm 0.1$   $\epsilon\text{Nd}$  on repeat analyses (Liu et al., 2017). Given this, we expect that we can achieve a smaller scale of variability in the Mississippi, especially when considering only the clay ( $<2\ \mu\text{m}$ ) fraction.

#### 4.2.1 Neodymium in North America

North America has a large database of Nd isotope compositions which, in general, correspond with the crystallization ages of the igneous/metamorphic bedrock (Fig. 4.1). The

oldest rocks, dating from the Archean, which comprise the Canadian Shield, have  $\epsilon\text{Nd}$  signatures that range from -26 to -17 (Patchett, Ross, & Gleason, 1999). Younger rocks, which comprise the bedrock of much of the southwest and mid-continental United States, have  $\epsilon\text{Nd}$  values that range from -17 to -13 (D. J. DePaolo & Wasserburg, 1976). Younger bedrocks from the Grenville region have  $\epsilon\text{Nd}$  values from -13 to -3 (Bream et al., 2004; James D Gleason, Patchett, Dickinson, & Ruiz, 1994; J.D. Gleason, Patchett, Dickinson, & Ruiz, 1995). This signature dominates the rocks of the Appalachian orogeny through recycling of earlier rocks during that phase of magmatism and deformation. Studies have shown that this  $\epsilon\text{Nd}$  signature propagates far westward and is present in most of the sedimentary rocks younger than 450 Ma (Patchett et al., 1999). Although bedrock sources formed or eroded from the Laramide and Corderillan (30 to 275 Ma) orogenic events (hashed area in Figure 4.1) have more positive  $\epsilon\text{Nd}$  values, Patchett et al. (1999) did not see the impact of this change in chemistry in sedimentary rock postdating these events. However, they proposed that recent sediment eroded from these regions should show a shift in isotopic composition as a result of these new orogenic sources.

#### 4.3. Mississippi River and Delta

The Mississippi River is the 4<sup>th</sup> largest drainage system in the world in terms of drainage area, reaching into Canada and flowing southward for almost 4000 km before eventually emptying into the Gulf of Mexico (J.P.M. Syvitski & Milliman, 2007). It is the largest river in North America comprised of five main drainage systems that flow across geologically diverse terrane and supply sediment from the headwaters down to the Mississippi delta. The Missouri, Arkansas, and Red Rivers drain the western part of North America, with their headwaters reaching the Rocky Mountains in the West. The Upper Mississippi, Illinois, and Ohio River

drain the Canadian Shield and Appalachian Mountains to the north and east of the United States, respectively (Fig. 4.1).

Figure 4. 1 Map of North America showing the trace of the trunk Mississippi River and its major tributaries. Black hexagons show the location of samples used in this study. Shading indicates regional average Nd isotope composition from Patchett et al. (1999) that define the large scale heterogeneity of  $\epsilon_{Nd}$  in the source regions.

#### 4.3.1 Historic and Modern Hydrology

Most of the sediment discharge in the Mississippi River has historically come from the Missouri River, while most of the water discharge is derived from the Ohio (Alexander et al., 2012; Meade & Moody, 2010). The Missouri River still provides much of the suspended sediment load, but this number has been checked by dams and water control structures built on the river in the 1960s (Mason et al., 2017; J.P.M. Syvitski, C., Kettner, & Green, 2005). This is

most evident when looking at historic measurements in which suspended sediment load plummeted from 500 Mt/yr to about 100 Mt/yr after the addition of the Ft. Randall and Big Bend dams on the Missouri River (Mason et al., 2017). Locks and dams have perhaps been responsible for the greatest change in hydrology and sediment supply in the basin. While wicker lock structures were built on the Ohio River as early as the mid-1800s, it was not until the 1940s-1960s that major changes to the Mississippi River and its tributaries were constructed (Alexander et al., 2012; Mason et al., 2017). While not a dam, the Old River Control Structure, used to control flooding in the lower reaches of the Mississippi, cut off flow from the Red River to the lower Mississippi River in 1963 and diverts 30% of the Mississippi discharge to the Atchafalaya Basin.

The construction of levees for flood control has also led to a decrease in sediment reaching the terrestrial delta. These structures effectively channelize the river and cut off sediment supply to the floodplain and delta plain. As early as 1718-1727, French colonists built 4 foot high levees along the banks of the river in New Orleans to try and counteract the floods that occurred almost yearly (Colten, 2006; D. Rogers, 2005; J. D. Rogers, 2008). These small structures, built in the style of European levees, were not very effective on the large-scale floods of the Mississippi. For the next 100 years, levees were intermittent at best, and covered only small sections of the river. It was not until the Swamp Act of 1849-1850 (following a series of bad flood years) that the government took on the issue of flood control along the Mississippi. In the late 1800s, a series of catastrophic floods led to a more comprehensive and higher levee complex. This cycle of flooding and levee raising continued until the historic flood of 1927, after which levees were raised to a height of almost 25 feet at Lake Pontchartrain to prevent storm surge (J. D. Rogers, 2008)(Fig. 4.2). After this flood, levee systems along the entire Mississippi

and its tributaries were raised, effectively channelizing the Mississippi and cutting off sediment supply to the floodplain.

Figure 4. 2 Development of the Mississippi River levee elevations since the late 19<sup>th</sup> century. Redrawn from Moore (1972).

All of these manmade alterations to the modern regime within the last 60 years have culminated in a significant loss of sediment to the Mississippi River delta. Blum and Roberts (2009) have estimated a reduction of nearly 60% of sediment delivery to the delta and (Boesch et al. (1994) 25% of wetland loss in coastal Louisiana. This has exacerbated subsidence and loss of land and natural fishery areas along the entire coast of Louisiana, which had, up until recently, supported a thriving delta community.

#### 4.3.2 Mississippi River Delta Complexes

Deltas around the world started forming around 7 ka in response to sea level rise stabilization following the end of the Pleistocene. In the 1950s, the classification of deltas and recognition of delta building sequences were extensively studied (McIntire, 1954), (Station & Kolb, 1958). Studies in the Mississippi River delta interpreted and defined 6 major delta progradation sequences (Coleman, Roberts, & Stone, 1998; D.E. Frazier, 1967; Harry H Roberts, 1997) (Fig. 4.3).

Figure 4. 3 Map of the Mississippi delta region showing the defined delta complexes spanning the time since 7.5 ka (Bentley, Blum, Maloney, Pond, & Paulsell, 2016). Black marker shows the location of the core analyzed in this study and the Old River Control Structure.

In general the delta plain is comprised of a series of delta complexes. A river transports sediment to a delta complex until there is no more accommodation space. When sediment transport becomes inefficient the river avulses to a new section of the delta plain thereby creating a new delta complex. For the Mississippi, the delta complexes are defined as the Maringouin dated to 7.5 to 5.5 ka, the Teche from 5.5-3.5 ka, the St. Bernard 4-2 ka, the LaFourche 2.5-0.5 ka, the Plaquemines/Modern 1.3 to present, and the Atchafalaya from .5 ka to present. These delta complexes have main points of progradation throughout their life; however, it is important to note that distributaries still remain active forming subdeltas in the other regions of the overall delta plain. This study specifically focuses on the Plaquemines and the St. Bernard subdeltas.

## 4.4 Methods

### 4.4.1 Sampling

Grab samples from the modern river within the modern levees were taken from each major tributary of the Mississippi and from the Mississippi trunk directly below major confluences. These were then separated until only the clay remained for Nd isotope analysis (Fig. 4.1, locations in Appendix C Supplemental Table 4.1). In addition, a 500cm core was extracted from within the Mississippi Delta (Fig. 4.4). This core was taken back to the lab, then cut and sampled for dating (OSL, radiocarbon,  $^{210}\text{Pb}$ , and  $^{137}\text{Cs}$ ), grainsize, and isotope work as described below. Facies were interpreted using Coleman and Gagliano (1964).

### 4.4.2 Radiocarbon

An in situ shell, found within the core, was sent to the NOSAMS laboratory for analysis; then processed using the marine 13 curve in CALIB Radiocarbon Calibration program (Hughen et al., 2009)(Stuiver et al. 2019). Since the shell was collected in what is interpreted to be marine deposits in Breton Sound, a marine correction defined regionally in the Gulf of Mexico of 500 +/- 300  $^{14}\text{C}$  is used to account for the full variability within the reservoir (Törnqvist, Rosenheim, Hu, & Fernandez, 2015).

### 4.4.3 Optically Stimulated Luminescence Dating

Age control for Holocene deposits was determined using optically stimulated luminescence (OSL) dating of quartz in sediments. This technique dates the last time the sediment was exposed to sunlight, presumably during transport. It is widely applied to quartz-bearing sediment deposited in the past 200 ky (Rhodes, 2011). Depositional ages of sediment were determined by OSL dating of quartz sand following the single-aliquot regenerative dose

method (Murray & Wintle, 2000). While OSL dating can be challenging in fluvial environments, deposits from these settings can be accurately dated by selecting depositional facies most likely to have been reset by sunlight exposure (Fuchs & Owen, 2008; Rittenour, 2008; Wyshnytzky, Rittenour, Nelson, & Thackray, 2015). Samples were processed at the Utah State University Luminescence Laboratory. This study targeted horizontally bedded sand and silt beds from fluvial deposits to reduce the influence of incomplete resetting (partial bleaching) of the luminescence signal.

Three OSL samples were collected in a dark room and shipped to Utah State University (USU) Luminescence Laboratory for optically stimulated luminescence (OSL) dating of quartz sand (Huntley, 1985; Murray & Wintle, 2000). Samples were opened under dim amber light (~590 nm) and sediment from the inner portions of the sample tubes was sieved and treated with hydrochloric acid to dissolve carbonates. Then chlorine bleach was used to remove organic material. Heavy mineral separation (sodium polytungstate, 2.7 g/cm<sup>3</sup>) and concentrated hydrofluoric and hydrochloric acids were used to remove feldspars, etched quartz grains, and prevented formation of fluorite precipitates (see (Rittenour, 2008) for details). The samples were re-sieved to remove the <63µm grain-size fraction of etched quartz and any partially dissolved feldspars (Wintle & Murray, 1997). Purity of the samples was checked using infrared (IR) stimulation on all aliquots.

Representative sediment around the samples was collected for dose rate analysis and submitted for ICP-MS and ICP-AES analyses of K, Rb, Th, and U content. In-situ gravimetric moisture content was measured for all samples. For those with <5.8% measured water content, we used an average value of  $5.8 \pm 3.0\%$  to represent the moisture content over burial history. Dose

rate calculations include cosmic dose rate contribution by using sample depth, elevation, and longitude/latitude following Prescott and Hutton (1994), influence of water attenuation, uncertainty in elemental measurements and dose rate conversion factors (Aitken, 1998; Guerin, Mercier, & Adamiec, 2011).

Figure 4. 4 Aerial photograph of the Mississippi delta. Inset photograph is a closeup of the region around the core location showing the relationship of the seaward levee and the Mississippi River channel (Hoffman, 1988; Ross & Villeneuve, 2003; Dahl, Holm, Gardner, Hubacher, & Foland, 1999).

#### 4.4.4 Pb-210 and Cs-137

Cesium-137 and Lead-210 are commonly used for age control when investigating historic Quaternary sedimentary deposits (C. A. Nittrouer, Sternberg, Carpenter, & Bennett, 1979; Noller, 2000).  $^{210}\text{Pb}$  has a geologically short half-life that can date with high confidence modern sediment deposited within the last 150 years. This makes it more effective than radiocarbon dating for very recent deposits. Similarly,  $^{137}\text{Cs}$ , with its short half-life and introduction into soil at a detectable level in 1954 from nuclear bomb testing, can help calibrate  $^{210}\text{Pb}$  and provide modern age control on sediment (Tylmann, W., Bonk, A., Goslar, T., Wulf, S., & Grosjean, M., 2016).

Samples for  $^{137}\text{Cs}$  and  $^{210}\text{Pb}$  detection were dried in an oven at  $55^{\circ}\text{C}$ , then weighed and pulverized using a mortar and pestle to homogenize the particle size. Samples were then packed to fill 12 mm diameter plastic well vials with an air tight seal. Samples were then run after three weeks (to allow sufficient time for secular equilibrium to be reached) on a Canberra SAGE gamma well detector that measures up to 2000 keV for 24 hours. Energies at respective photopeaks were measured as follows:  $^{137}\text{Cs}$  at 661.7 keV,  $^{210}\text{Pb}$  at 46.5 keV,  $^{214}\text{Pb}$  at 295 keV and 351 keV, and  $^{214}\text{Bi}$  at 609 keV. The units of measurement for the radioactivity used in this study are disintegrations per minute (dpm) or  $1/60^{\text{th}}$  of a Becquerel (Bq).

#### 4.4.5 Nd and Sr isotopes

Care was taken to decarbonate samples (core and grab samples) prior to analysis with 20% acetic acid because Sr isotope compositions are strongly controlled by carbonate compositions and this study targets the siliciclastic sediment compositions only. Decarbonation lasted for six days until no further fizzing was observed when samples were exposed to unreacted acid. Samples were washed by deionized water and dried before being ground into

powders. Isotopic compositions of Nd and Sr were determined by Finnigan Neptune multi-collector inductively coupled plasma mass spectrometer (MC-ICP-MS) at the Woods Hole Oceanographic Institute. Nd and Sr isotope analyses were corrected against La Jolla Nd standard  $^{143}\text{Nd}/^{144}\text{Nd}=0.511847$  and NBS987 standard  $^{87}\text{Sr}/^{86}\text{Sr}=0.710240$ . Procedural blanks were 20–25 pg for Sr and 50–70 pg for Nd. We calculate the parameter  $\epsilon_{\text{Nd}}$  after (DePaolo and Wasserburg, 1976) using a  $^{143}\text{Nd}/^{144}\text{Nd}$  value of 0.512638 for the Chondritic Uniform Reservoir (CHUR) (Hamilton, Onions, Bridgwater, & Nutman, 1983).

#### 4.4.6 Grain Size

Grain size analysis followed the procedures of Hülse and Bentley (2012). A small amount of sample was placed into a cleaned 50 ml plastic centrifuge tube and 5–7 ml of sodium metaphosphate solution was added. The tube was capped and vortexed to deflocculate clay-sized sediment and separate organic particles. The sample was poured through an 850  $\mu\text{m}$  sieve and funneled into a 15 ml glass test tube. After centrifuging and removing the clear supernatant, 2–3 ml of sodium metaphosphate and 5 ml of 30%  $\text{H}_2\text{O}_2$  were added. Tubes were vortexed again and then put into a hot bath that was heated to 70°C overnight. Reacted supernatant was then removed and 5 ml of sodium phosphate were added. Samples were then rinsed with deionized water, transferred into 50 ml plastic centrifuge tubes, and topped with sodium metaphosphate into a sample solution of up to 40 ml. Samples were vortexed again prior to grain size analysis on a Beckmann Coulter LS13 320 laser diffraction particle size analyzer at LSU. The obscuration of all running samples in the aqueous liquid module (ALM) was between 8–12 %.

## 4.5. Core Stratigraphy and Age Control

### 4.5.1 Core Stratigraphy

From 500 to 463 cm the core is a compact, massive, clay deposit marked with a sharp boundary on top. This transitions to silt interbedded with sand from 463 to 382. Silty deposits followed by a sandy bed with shell hash then moves to another dark, compact, massive clay deposit with shell hash beds (382 to 314 cm). A gradual transition is made into a thick series of coarsening upward interbedded sands and silts which span from 314 to 230 cm. A sharp boundary marks the transition to a fining upwards sand layer which is found from 230 to 175 cm. From 175 to 66 cm sands interbedded with silt and sand fine upwards towards more silt and clay-rich deposits. The core stratigraphy changes abruptly above 66 cm where the presence of organic material within the clay and silt becomes predominate to the surface.

### 4.5.2 Bay/Estuary

Dark, reduced, compact massive clay deposits were interpreted as bay/estuary deposits (Fig. 4.5). Sandy storm deposits can be found within the clay together with whole shells mixed with shell hash. The bay/estuary deposits are found at the base of the core from 463 to 500 cm and further up the core from 314 to 382 cm, indicating two separate intervals of marine dominated sedimentation in this location. An in situ oyster shell at a depth of 480 cm was dated by radiocarbon methods, constraining the age of the lowest bay deposits to 3.98 +/- 0.4 ka.

### 4.5.3 Prodelta/Delta Front

Prodelta/delta front sequences are represented in this core by coarsening upward deposits of interbedded silt and sand with intermittent clay beds.

Figure 4. 5 Lithology log of the section cored in the Mississippi delta showing major % of sand, silt, and clay together with  $\epsilon Nd$  values. Age control shown on left (methods described in text). Interpreted sedimentary environments and correlated delta complexes/ depositional events on the right.

These deposits are found within the core from 382 to 463 cm and from 230 to 314 cm. This facies is interpreted to represent as a prograding delta followed by a transgression of delta lobe which avulsed away from the core location, leading to a marine environment. The delta lobe then moved back towards the core location leading to reactivation of the prodelta/delta front. The upper prodelta/delta front sequence, from 230 to 314 cm is dated by OSL to  $2.07 \pm 0.3$  ka at 290 cm of depth. A very sandy deposit atop the prodelta/delta front sequence (230-175 cm) is interpreted as a channel deposit. This channel deposit yielded OSL ages of  $1.92 \pm 0.4$  ka.

#### 4.5.4 Floodplain

The top 175 cm of the core are interpreted to represent fluvial floodplain environments. The interbedded sand and silt from 66 to 175 cm are indicative of levee overbank flood deposits in a terrestrial delta. An OSL date at 150 cm yielded an age of  $1.39 \pm 0.04$  ka. Dating the sediment at the top of the core showed a  $^{137}\text{Cs}$  peak at 10 cm depth, but this is absent by a depth of 20 cm, thus 15 cm is interpreted here as 1954 (Fig 4.5) (Supplemental Figure 4.1; Appendix C).  $\text{Pb}^{210}$  dating indicated an accumulation rate of 1.73 cm/yr for the top 70 cm of the core.

#### 4.6. Nd Isotopes

Samples from modern tributaries of the Mississippi River show that those draining the western parts of the basin are more  $\epsilon\text{Nd}$  positive than rivers derived from the north and east. We also note a general trend to more positive  $\epsilon\text{Nd}$  values in the trunk river, moving downstream (Fig. 4.6). The greatest change in the Mississippi occurs downstream of the Missouri confluence after which the main trunk of the Mississippi does not show much variation ( $\epsilon\text{Nd} = \sim 10.5$  to 11.5).

Nd isotopic values do not vary greatly throughout the core within a range of  $\epsilon_{\text{Nd}} = -10.98$  (10 cm) to  $-8.88$  (250 cm). In general, the isotopic values from 250 to 500 cm are more positive than the  $\epsilon_{\text{Nd}}$  values above 250 cm. There is a significant shift to more negative  $\epsilon_{\text{Nd}}$  values in the top 66 cm of the core ( $\epsilon_{\text{Nd}} = \sim 10.2$  to  $11.0$ ), which coincides with a change in sedimentation to more organic-rich clay material (Fig. 4.5 and 6).

Figure 4. 6 Present day downstream evolution in A) Nd and B) Sr isotope compositions for clay separates from the trunk and major tributaries of the Mississippi. Note the gradual drift to more positive  $\epsilon_{\text{Nd}}$  values from source to the river mouth.

## 4.7. Discussion

### 4.7.1 Sedimentology

Based on OSL and radiocarbon ages provided by this study and the delta evolution models (Frazier 1967; Roberts 1997), this core captures two prodelta/delta front sequences of the

St. Bernard delta complex separated by a bay/estuarine environment, found between 500 and 175 cm depth (Fig. 4.5). The prodelta/delta front sequences loosely correlate with two phases of St. Bernard delta building, found in Frazier (1967), which we date to just after  $3.8 \pm 0.4$  ka (radiocarbon) and between  $2.07 \pm 0.3$  ka and  $1.92 \pm 0.4$  ka. The St. Bernard delta complex is followed upsection by sediment that most likely represents occupation of the Plaquemines delta-building sequence, evident here by the OSL date of  $1.39 \pm 0.4$  ka at a depth of 150 cm. This change is represented by overbank levee/floodplain deposits that, as described earlier, change abruptly upsection. The sedimentation in the top 66 cm of the core is very fine grained and organic rich. We acknowledge here that these facies are likely anthropogenically influenced by the construction of both fluvial and seaward levees near the core site. USGS maps of the core site show the construction of a seaward levee between 1956 and 1966. This results in a reduction of sedimentation rates in the top of the core shown by the  $^{210}\text{Pb}$  and  $^{137}\text{Cs}$  results. As mentioned previously the  $^{137}\text{Cs}$  dating methods indicated ~15cm of depth corresponds to 1954, which implies that 63 years of sedimentation are represented in approximately the top 15 cm of the core. This corresponds to a sedimentation rate of 0.23 cm/yr. The  $^{210}\text{Pb}$  derived sedimentation rate over longer timescales (last 150 yr) is 1.73 cm/yr. We interpret the lower sedimentation rate within the upper 15 cm to be a result of the construction of the seaward levee in the 1960s, cutting off sediment supply during storm events (Fig. 4.4).

Extrapolating the  $^{210}\text{Pb}$  date sedimentation rate of 1.73 cm/yr rate from 15 cm to 66 cm depth, where there is an abrupt change in lithology (to more organic rich sediment), indicates ~30 years of sedimentation in that depth interval (Fig. 4.5). This implies that the date at 66 cm depth is 1924, 30 years earlier, thus it is interesting the change in lithology observed closely correlates with a large increase in levee height around 1915 (D. Rogers, 2005)(Fig. 4.2). It is at

then corroborated through core lithology and age dating that at this point in time significant fluvial deposition was cut off from the site and any deposition after this date occurred when the seaward side of the levee was potentially breached by large hurricanes (eg. Besty:1965 or Katrina:2005).

#### 4.7.2 Nd Interpretation

Nd isotope values for the Mississippi River sediment grab samples show that the Upper Mississippi, Illinois and Ohio River plot towards more negative  $\epsilon\text{Nd}$  values (-11.5 to -13), while the Missouri, Arkansas and Red Rivers plot more positive (-10.5 to -9.5) (Fig. 4.6A). The western tributaries seem to have  $\epsilon\text{Nd}$  signatures that are strongly influenced by erosion from the Grenville and possibly the Laramide/Cordilleran orogenic belts, while the eastern and northern tributaries source more  $\epsilon\text{Nd}$  negative Grenville and Archean bedrock (Fig. 4.1 and 6).  $^{87}\text{Sr}/^{86}\text{Sr}$  values of the tributaries also show regional variability, with the Ohio being marked by relatively higher values and the Missouri with lower values (Fig. 4.6B). However this study determined many of the tributaries have similar  $^{87}\text{Sr}/^{86}\text{Sr}$  values to each other and consequently making Sr isotopes a poor provenance indicator in this system.

When examining the downstream evolution in  $\epsilon\text{Nd}$  values, the Missouri makes the single largest contribution to the main trunk of the Mississippi River when it joins with the Upper Mississippi (Fig. 4.6). This tributary effectively pulls the mixed Mississippi sediment  $\sim 2$   $\epsilon\text{Nd}$  points more positive after mixing with the main stream. In contrast, the Illinois is relatively negative compared to the downstream mixed sediment, indicating the weak influence this stream has on the mixed sediment. This is not surprising, given the modest relative discharge of the Illinois compared to the Missouri River (5.9 Mt/yr vs. 56.9 Mt/yr respectively). Moving

downstream, the other tributaries affect the overall  $\epsilon\text{Nd}$  values of the sediment in the Mississippi very little. Overall though, variation between the eastern/northern and western tributaries can be seen and quantified, and therefore used as a provenance tool in mixed sediment from the Mississippi River.

To compare to previous Nd and Sr isotopic sediment measurements, our data are plotted with that from Goldstein and Jacobsen (1988) that were taken from the main tributaries and trunk of the Mississippi River (Fig. 4.7). We see that the  $\epsilon\text{Nd}$  values of the core sediments plot close to both our new and older analyses of Mississippi and Missouri River sediments, i.e., around  $\epsilon\text{Nd} -10$ , which correlates with the range of  $\epsilon\text{Nd}$  values associated with the Grenville province (-13 to -7)(Fig. 4.7; Bream et al., 2004; James D Gleason et al., 1994; J.D. Gleason et al., 1995).  $\epsilon\text{Nd}$  values from core sediment mainly cluster around the samples taken from the modern Missouri, Red and Arkansas Rivers (Fig. 4.7A). These values are associated with erosion from the more  $\epsilon\text{Nd}$  positive Laramide/Cordilleran and Grenville sources that dominate the western parts of the basin.

If a closer look is taken at the Sr-Nd data from the core samples, a general up-core trend can be distinguished (Figs. 4. 3 and 7). Samples from what is interpreted as St. Bernard delta deposits plot towards more positive  $\epsilon\text{Nd}$  values and lower  $^{87}\text{Sr}/^{86}\text{Sr}$ , while those from the Plaquemines and the Modern deltas plot with more negative  $\epsilon\text{Nd}$  and greater  $^{87}\text{Sr}/^{86}\text{Sr}$  values (Fig. 4.7B). This can also be seen when the core is compared against the average  $\epsilon\text{Nd}$  values for western and eastern/northern tributary sediments (Fig. 4.8). On average, samples from the St. Bernard delta have an  $\epsilon\text{Nd}$  value of -9.6, while those from the Plaquemines have a value of -10.0

(Fig. 4.5). The most significant shift in the data are the  $\epsilon\text{Nd}$  values in the top 66 cm of the core which have an average of  $\epsilon\text{Nd}$  value of -10.6.

Figure 4. 7 A) Cross plot of Nd and Sr isotope values for both the cored samples and the modern Mississippi River samples compared with earlier measurements by Goldstein & Jacobsen (1988). Colored bands show the major Nd isotopic divisions of continental North America as shown in Figure 4.1. B) Cross plot of Nd and Sr isotope values of only the core samples and their interpreted correlation with the defined delta complexes of the Mississippi (see Fig. 4.3).

Slightly warmer and drier climate during the time of the St. Bernard delta building (2–4 ka) is hypothesized to have reduced the occurrence of mega floods (Knox, 1993), however this drying could have resulted in reduced vegetation cover in the western parts of the Mississippi catchment. A drier climate would lead to floodplain destabilization and therefore a greater sediment supply from the western drainages. The climate regime in the last 1 ky is both cooler and wetter (Aharon & Dhungana, 2017; Knox, 1993), which would lead to greater vegetation cover and a reduced supply of sediment from the west, thereby potentially explaining the shift towards more negative  $\epsilon\text{Nd}$  values at the start of the Plaquemine/Modern delta sedimentation.

While the general trend towards more negative  $\epsilon\text{Nd}$  values in the Plaquemines/Modern compared to the St. Bernard samples may reasonably be within uncertainty, the top 66 cm and modern sediment cannot be accounted for in this way. While the more negative shift in  $\epsilon\text{Nd}$  in the top 66 cm could be associated with increased erosion within the northern and eastern tributaries of the Mississippi River, modern river samples do not suggest this to be the case (Fig 4.6A). Analysis of  $\epsilon\text{Nd}$  from within the Upper Mississippi and Ohio Rivers presently show that they contribute very little to the main stream sediment flux (Fig. 4.6A). Conversely, reduced sediment flux from the western tributaries since the 1920s could produce a similar trend in isotope composition. While damming of these streams might have caused the up-core variation in isotope values, historical data shows that sediment flux did not reduce significantly until the 1950s and 1960s (Mason et al., 2017), when large-scale damming of these tributaries and the installation of the Old River Control structure in Louisiana occurred.

Figure 4. 8 Variations in the  $\epsilon_{Nd}$  values in the core plotted against depth and compared with the average values from the modern western and northern/eastern tributaries.

We argue the  $\epsilon_{Nd}$  shift towards more negative values in the top of the core can best be explained by the enhancement of levees along the Mississippi River, which cut off deposition of fluvial sediment to the core site in the 1920s (Fig. 4.4 and 5). After this, the only sediment the core site received after the construction of the higher levees would be from storm deposits or

longshore drift suspended sediments sourced from east of the Mississippi River delta (eg. Pearl and Mobile Rivers) until the construction of the seaward levee in the 1960s. Since eastern rivers are supplied by sediment from more negative  $\epsilon\text{Nd}$  source terranes (Fig. 4.1) this could help explain the sharp negative trend in  $\epsilon\text{Nd}$  found at the top of the core. However  $\epsilon\text{Nd}$  data from these rivers does not exist and warrants further investigation.

#### 4.8. Conclusions

We show that the western and eastern/northern drainages of the Mississippi River have distinctive Nd and Sr isotopic signatures. The western tributaries have more positive  $\epsilon\text{Nd}$  values, while the eastern and northern tributaries have more negative  $\epsilon\text{Nd}$  values. Most of the detrital grab samples from the modern river show a trend towards western (Missouri)  $\epsilon\text{Nd}$  values, with little input from the northern and eastern tributaries. While most of these samples derive their provenance from Grenville sources (Fig. 4.1, 7), there seems to be a general trend towards less negative values as you move from the west to southeast when looking at the  $\epsilon\text{Nd}$  values derived from the modern tributaries. In general, however, on a continental scale, the more positive  $\epsilon\text{Nd}$  values that characterize the youngest Laramide/Cordilleran orogenic events have not significantly impacted the overall Grenville-dominated Nd isotopic signatures of the modern Mississippi sediment.

Two phases of St Bernard delta building (2–4 ka) are captured and dated to  $1.92 \pm 0.4$  to  $3.98 \pm .4$  in this core, as well as the beginning stages of the Plaquemines/Modern subdelta complex ( $<1.3$  ka). In this study, overbank natural levee and floodplain aggradation are seen to be significantly curtailed by human influence, effectively slowing the accumulation rate going from  $1.73$  cm/yr before levee construction to approximately  $0.23$  cm/yr in the top 66 cm of core.

With significant changes such as these, it is evident why the Mississippi Delta is presently facing such problems with subsidence and floodplain nourishment.

Isotope compositions of sediment from the Mississippi over the last 3 ka have remained consistent. With an average value of  $-9.9 \text{ } \epsilon\text{Nd}$ , this is slightly less negative than other values recorded from the modern system at  $-10 \text{ } \epsilon\text{Nd}$  (S. J. Goldstein & Jacobsen, 1988). This can most likely be explained by the more positive  $\epsilon\text{Nd}$  values associated with the St. Bernard delta sequence derived from western sources. The sharp trend towards more negative values in the top 66 cm of the core is interpreted to be anthropogenically driven. With the construction of more robust levees along the Mississippi River in the 1920's the floodplain was cut off from overbank fluvial deposits, likely only receiving sediment from major storms which resuspended sediment from sources to the east of the Mississippi River with a more negative  $\epsilon\text{Nd}$  isotopic signature.

## CHAPTER 5. CONCLUSIONS

In general, this dissertation seeks to understand the provenance relationships within the Mississippi River catchment. Chapter 1 enforces the importance of western North America, specifically the Missouri River, in regards to sand flux to the Mississippi. Despite the fact the source rock containing younger ages zircon only represent a small area within the Mississippi and associated drainages, young mountain building followed by later glaciation events have created a sediment rich, unconsolidated source accessed by the modern rivers in western North America. When compared to other zircon studies, instability in sediment flux is seen throughout the river which is interpreted here as anthropogenic influence to the system.

Using apatite REE and trace element data as a provenance indicator demonstrated the limitations of traditional methods for interpreting large-scale detrital populations. This study found element ternary plots a useful tool for categorizing geochemical data of single grain populations. The benefits of using categorical data are important for the application of statistical unmixing models for provenance interpretations. Overall, regional sediment contributions compared favorably with zircon from the same sample, which reinforces the use of this mineral as a provenance tool. This method could be further improved through a more rigorous categorization process using hierarchical clustering and additional analysis with the microprobe to classify grains by OH, Cl, and F.

Finally, the Nd and Sr isotopes used to interpret provenance in the Mississippi delta over the last 3 ky show similar findings to both zircon and apatite. Results display that older  $\epsilon\text{Nd}$  signatures of Grenville origin largely control the signature of the Mississippi River. Within the core, delta deposits have more positive  $\epsilon\text{Nd}$  values at the base that generally trend towards more

negative in the most recent sediment. The most extensive shift is seen within the last ~100 years which coincides with large-scale engineering projects along the Mississippi and within the delta. This shows that, within the delta, modern anthropogenic affects have had a significant effect on sedimentation within the delta.

When viewed holistically these studies highlight the importance of human controls on the modern Mississippi River, and suggest that these recent alterations have fundamentally changed the way in which sediment is transported from source to sink. Fluvial system are complicated by nature, making provenance interpretation difficult even without accounting for modern alteration of the drainage. Traditional geologic practices of using modern rivers as analogues for their ancestral fluvial complexes must therefore carefully consider alteration to the catchment before direct comparison can be made. Unfortunately, the way in which rivers around the world have been altered in the last 100 years has affects that are far more serious than just geological interpretation of the past. These changes are currently endangering coastal and wetland environments which sustain a variety of wildlife and local communities. Studies involving the changes in these fluvial systems are direly important for the future of coastal sustainability and preservation as a whole.

## APPENDIX B. SUPPLEMENTARY DATA FOR CHAPTER 3

Supplementary Figure B. 1 A reference version of the cladogram found in Belousova et al. (2002) used to discriminate apatite source rock.

Supplementary Figure B. 2 Cross plots of chondrite normal Ce/Yb against total weight % REEs with fields showing the predicted source rock type from Morton and Yaxley (2007) and Belousova et al. (2002). (A) Missouri, (B) Northern Tributaries, (C) Southwest Tributaries, and (D) Ohio.

Supplementary Figure B. 3 Cross plots of  $\text{Eu}/\text{Eu}^*$  against Y concentrations for single apatite grains with fields showing the predicted source rock types from (A. Morton & Yaxley, 2007) and (Belousova et al., 2002), divided by tributary. (A) Missouri, (B) Northern Tributaries, (C) Southwest Tributaries, and (D) Ohio.

Supplementary Table B. 1 Laser Setting

Spot Size	Shot Frequency	Laser Energy	Burst Count	Gas Flow
25um	10 Hz	30%	700-800	700 l/min

Supplementary Table B. 2 Table showing Statistics and Reproducibility of Apatite Standards

## CURRICULUM VITAE

Brittney Anne Gregory  
75 Oak St. Mobile AL 36608  
email: [brikkagr84@gmail.com](mailto:brikkagr84@gmail.com)

### Education

2011 M. S. Geography, The University of North Texas Thesis title: Geologic and Lithic Analysis of the Red River Cache. Dr. Reid Ferring, advisor

2006 B. A. Applied Anthropology, University of North Texas

2019: PhD Geology and Geophysics, Louisiana State University

### Professional Work Experience

2010-present Consulting geomorphologist-geoarchaeologist.

2008-2010 Teaching Assistant, Department of Geography, University of North Texas.

2006 Wenas Creek Mammoth Project (Dr. Pat Lubinski, Central Washington University).

Regional Experience: Texas Rivers and Streams including the Guadalupe, San Antonio, Trinity, Colorado, and Brazos. Paleoindian coastal sites in Florida, Chihuahuan Desert including Fort Bliss, Trans-Pecos, and Lower Pecos. Southern Great Plains and periphery with work in South Eastern New Mexico and the Canadian Breaks. Loess landscapes on the Columbian Plateau in Central Washington and Idaho.

Research interests: Geoarchaeology, geomorphology, paleoenvironmental reconstruction, and fluvial geology.

### Publications, Journal Articles, and Chapters in Edited Books

Rink, W. J., J. S. Dunbar, G. Doran, C.D. Frederick and B. Gregory

2012 Geoarchaeological investigations and OSL dating evidence in an Archaic and Palaeoindian at the Helen Blazes Site (8BR27), Brevard County, Florida. Florida Anthropologist 65(1-2): 87-107.

### Contract and Project Reports

W. Nicholas Trierweiler, Brittney Gregory, Charles Frederick, and Jon Dowling  
2013 Geoarcheological Investigations of the Henderson Street Borrow Pit in the Trinity River Floodplain, Tarrant County, Texas. Ammaterra Environmental, Inc. Report No. 44, Texas Antiquities Permit No. 6381. Austin, Texas

Quigg, J. Michael, Paul M. Matchen, Charles D. Frederick, Robert A. Ricklis, Brittney Gregory, David Maki and Mark Bateman, with contributions by J. Phil Dering, Jeffery R. Ferguson, Michael D. Glascock, Michelle Hamilton, Bruce L. Hardy, Mary E. Malainey, Linda Perry, David G. Robinson, M. Steven Shackley, Grant Smith, M. Kate Spradley, J. Byron Sudbury, Daniel J. Wescott, and Barbara Winsborough  
2013 Long View (41RB112): Data Recovery of Two Plains Village Period Components In Roberts County, Texas. Volume I. TRC Project No. 174542, Texas Antiquities Committee Permit No. 3721. Austin, Texas.

Brittney Gregory and Charles D. Frederick  
2012 Geoarchaeological Observations From the Wharton Levee Project. In The Archaeological Survey of the Proposed Wharton Levee System in the City of Wharton, Wharton County (Draft Report), by Somers, B., D. Barnes, K. Ellzey. Manuscript submitted to Submitted to U.S. Corps of Engineers, Fort Worth District, Contract No. W9126G-09D-0067 Delivery Order 0058. Gulf South Research Corporation, Baton Rouge, Louisiana.

Hatfield, Virginia, Charles D. Frederick, Brittney Gregory, and Karl W. Kibler  
2012 Archeological and geoarchaeological Investigations for the new Baylor University Football Stadium in Waco, McLennan County, Texas. Technical Report 88, Prewitt and Associates, Inc. Austin, Texas

Weinstein, Richard A., Charles D. Frederick, Timothy K. Perttula, Brittney Gregory, and Jennifer A. Kelly  
2012 Archeological and Geological Investigations at Site 41HM61, Hamilton County, Texas: Interim Report. Coastal Environments, Inc., Corpus Christi, Texas.

Frederick, C. D., Brittney Gregory and Phillip Shelley  
2011 Geomorphology. In The Boot Hill Site (LA 32229): An Oasis in the Desert, Eddy County, New Mexico, edited by Marie E. Brown, pp.77-98. TRC Environmental Inc., Albuquerque, New Mexico.

Frederick, Charles D. and Brittney Gregory  
2010 Geoarchaeological Reconnaissance of the XS Ranch, Bastrop County Texas. Appendix B in Thornton, Meg, T. Miller, and M. Doty Freeman, Phase I Archeological Investigations of Portions of the XS Ranch Property, Bastrop County, Texas, USACE No: 2008-280. ACI consulting, Austin Texas.
